At the session of the Medico-Legal Society, held February 8th, Pouchet spoke of the *accidents following the ingestion of spoiled meats.* Investigations have usually been conducted upon a toxicologic basis and have never given satisfactory results. Recently a physician who investigated an epidemic during which about fifty persons were attacked, with one death, became convinced that the symptoms were attributable to the consumption of spoiled pork. The most careful examination of this spoiled meat and of the excreta of two patients failed to reveal the presence of any toxic substance of vegetable, animal, or mineral origin; but from the meat a special microbe was isolated which proved to be the specific bacillus of the infective pulmono-enteritis of hogs. Inquiry elicited the information that an epidemic of hog cholera was raging at the time in the localities where the cases had occurred. These bacilli were not found in the excreta, but a virulent form of the bacillus coli was present.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting held January 5, 1897.

The President, Dr. Bernard Sachs, in the Chair.

ACUTE POLIOMYELITIS WITH INVOLVEMENT OF THE SEVENTH NERVE.

Dr. Terriberry presented a child, twenty months old, exhibiting this condition. It was a second child, and was born of healthy parents after a normal gestation and confinement. It was breast-fed and had developed normally. It walked without support at the age of seventeen months. It had never received any injury. On November 30, 1896, it was noticed to be restless and irritable, and the following morning there was high fever, with constant nausea and a profound prostration of the muscular system. The child appeared to be entirely free from pain and tenderness. When it was held up, the head fell on the left shoulder. Twenty-four hours later, the condition was not so severe. At this time the right side of the face was noticed to be unnatural, the eye being constantly open. It was not until the sixth day that it was able to balance itself on the feet. He had first seen the patient ten days after the onset of the attack. Examination then showed complete Bell's paralysis on the right side of the face. The right foot pointed outward, and there was a slight limp on this side. The knee-jerks were about normal. The galvanic current that could be tolerated produced good reaction on the unaffected side, but on the right side there was very slight reaction, and the formula was normal. Since that time the galvanic current had been applied two or three times a week. At the present time the eye was better and the limp was scarcely noticeable. There was slight flabbiness of all the muscles on the right side. The clinical picture presented by this case was quite typical of an acute poliomyelitis.

DR. JOSEPH COLLINS thought it was rather hazardous to make a diagnosis of anterior poliomyelitis in an infant who a month before had the beginning of such a destructive lesion, and who had now practically recovered. A much more probable interpretation would be an intoxication of the central nervous system, manifesting itself not only in the spinal cord, but in other parts of the nervous system, the infection not being sufficient to cause death of the ganglion cells. A fully developed anterior poliomyelitis was not compatible with the degree of improvement exhibited in this case.

DR. WILLIAM B. NOYES called attention to a class of cases that had been very prevalent of late, beginning with symptoms almost exactly like poliomyelitis, and characterized by unusually marked sensory disturbances, and recovering after three or four weeks. He could recall seeing since September about six such cases at the Vanderbilt Clinic. In these, the peripheral nerves were sometimes affected at the same time as the spinal cord. This would, perhaps, offer an explanation of the case just presented.

DR. TERRIBERRY said that in a neuritis of a mixed nerve one expected to find some sensory disturbance. There was entire absence of sensory disturbance in the case presented. He knew of no category in which the case could be placed except in that given—anterior poliomyelitis. The theory mentioned by Dr. Collins, of course, was recognized by all. Owing to the clinical features of the case he thought he was justified in so classifying it.

DR. COLLINS said that he would classify the case as an intoxication of the central nervous system. He believed pathologists stated now that the entire gray matter might be affected at the same time. It appeared to him to be a step backward to look upon the case as one of anterior poliomyelitis with bulbar involvement.

GRAVE'S DISEASE, WITH EDEMA OF THE EYELIDS.

DR. SCRATCHLEY, on behalf of Dr. Bishop, presented a woman suffering from Grave's disease. This condition had existed for four years and a half. The case was presented because of the edema of the eyelids, which had become much more manifest during the previous few weeks. Various methods of treatment had been tried, but the best results had followed the use of belladonna.

DR. J. ARTHUR BOOTH said that the kind of edema found in this case was not uncommon when the eyes were very prominent. In the case which he had reported previously there had been marked edema without prominence of the eyes. At the present time, he was experimenting with thymus extract in these cases.

COMPRESSION PARAPLEGIA IN POTT'S DISEASE OF THE SPINE, BASED UPON STATISTICS.

DR. V. P. GIBNEY read a paper with this title. He said that about nineteen years ago he had presented to this Society a paper on the same topic. The present communication included the cases seen since then. All authors agreed in relegating to laminectomy the cases apparently hopelessly incurable. It was true that in a few cases the results of operation had been extraordinarily good. He believed that iodid of potassium was an excellent remedy in these cases, and that it acted much more favorably when combined with proper support to the spine. He was accustomed to push the drug up to the point of tolerance. In a great many instances he also employed the Paquelin cautery. If one could secure rest in bed with traction on the head, he was convinced that recovery would be more rapid. He was still opposed to the use of electricity. The consensus of opinion seemed to be against the use of the term "compression myelitis," and in favor of the term "pressure paralysis."

The speaker said that he had been able to secure *final* results in 74 cases—33 males and 41 females. The disease was located in the cervical region in 5, in the upper dorsal in 38, in the mid-dorsal in 14, in the dorsal in 19, and in the lower dorsal in 8. There was no case in the lumbar region. Twenty-five of the 74 presented a small deformity, and 49 a prominent deformity. Four patients were over twenty-one years of age, 6 between twelve and fourteen, 9 between eight and twelve, 24 between four and eight, and 3 were under four years of age. The paralysis was recognized simultaneously with the deformity in 14; in 7 cases it was noted within three months, in 15 after six months, in 18 after twelve months, in 9 after two years, in 8 five years afterward, in 3 seven years afterward, and in 1 fourteen years after the deformity had appeared. The treatment consisted during the earlier years in the use of the Knight spinal brace, and, since 1879, chiefly in the application of a plaster of Paris cast with a snugly fitting jacket and a head-spring. In many cases of severe paralysis the wire cuirass or the Cabot frame was employed. Where there was much uncontrollable spasm, he had employed traction.

Forty-three of the cases were cured of the paraplegia, and the subsequent history showed that they remained cured. Eleven were improved at the time of leaving the hospital, and there was reason to believe that many of these were subsequently cured. Eight cases were unimproved and 13 died. Of the fatal cases, 4 seemed to die of myelitis. The longest duration of the paralysis was seven years, and recovery then followed. The shortest period was two months. Ten were paralyzed from four to six months. The average duration was about thirty-two months. Dr. Gibney said that in his former paper 58 cases had been reported. The total number reported by him was, therefore, 132.

A CONSIDERATION OF THE PARAPLEGIA OF POTT'S DISEASE WITH ESPECIAL REFERENCE TO THE RESULTS OF MECHANICAL TREATMENT.

DR. NEWTON N. SHAFFER presented a paper with this title, based on forty cases that had been treated among the poor in the out-patient service of the New York Orthopedic Dispensary. The treatment consisted in the application of the Taylor spinal brace, and keeping the patient in the recumbent position. The apparatus was adjusted to give firm support to the spinal column, but not to make special pressure. No internal medication was used. Thirty-two of the cases were under ten years of age, and 3 above that age, the oldest being forty-three years. Of the 40 cases, 33 were affected in the middle dorsal, upper dorsal, or cervical region. In 30 cases the disease had existed for five years before the occurrence of the paralysis; in 13 between one and two; in 1 for eleven, and in 1 for twelve years. It was not easy to determine just when the paralysis occurred in this class of patients. Of the 40 cases, 12 had abscess, and in 36 there was no *external* abscess. Four were benefited by opening the abscess, two abscesses opened spontaneously, two appeared after the occurrence of the paralysis, and one occurred after the paralysis had been cured. The deformity was slight in 14, marked in 21, and great in 5. The paralysis was no more severe in the cases having a great deformity. In 24 there was simply a motor paralysis; in 16 motor and sensory paralysis were combined. It was unusual for sensory paralysis to develop first in Pott's disease. The primary invasion of sensory symptoms, Dr. Shaffer said, always suggested malignant disease, a benign tumor, or some traumatic invasion of the spinal canal. In 14 cases the patients had been under treatment one year, or less, when the paralysis ensued. It should be remembered that these patients led a rough life, and that traumatism was extremely liable to occur. Paraplegia may occur even in cases most carefully and rigidly treated. There were three deaths among the 40 cases, but only one patient was still paralyzed at the time of death. This was a case of general tuberculosis.

There were 24 cases of simple motor paralysis, of which 21 recovered, and 3 were still under observation. There were 16 cases of combined sensory and motor paralysis, of which 11 recovered, and 5 were still under observation. Two patients died after recovery from the paralysis. Of the 32 recoveries, 15 walked well with exaggerated patellar reflexes, 5 walked well with normal knee-jerks, and of the remainder there was no record of the reflexes. It was evident from these observations that a large proportion of the cases of Pott's paraplegia would recover if the spinal column were adequately supported. Head-traction seemed to him useless except where the disease was very high up. He had also found that a plaster of Paris cast was not satisfactory because of its failing to give proper support. Of those remaining under observation about one-half had a reasonable hope of recovery. Of all the cases reported, only one had bed sores, and none had cystitis. Four patients had been under treatment from six to ten years, and were still paralyzed. It was probable that in these cases there had occurred a greater or less degeneration of the spinal cord, and, therefore, an operation was not likely to be of benefit. It would seem that after one year had elapsed, the chances of recovery rapidly diminished under mechanical treatment. A case of simple motor paralysis, it seemed to him, should not be operated upon. As long as the sensory tract was unaffected, surgical interference was not called for, and even where this tract was affected, the chances of recovery were excellent without such interference. The condition of the reflexes furnish a good indication of approaching paralysis. An exaggerated knee-jerk often announces the approach of paralysis, and is at least an indication that the patient should be kept quiet in bed. Whooping-cough, occurring in connection with dorsal deformity, is likely to be followed by a rapid increase of the deformity, and by the development of paraplegia. Paralysis from lumbar disease had been rare in his experience. Paraplegia might develop at any stage of the disease, even after apparent recovery. The average duration of simple motor paralysis was about seven months in these cases, and the average duration of simple sensory paralysis, ten months. In two cases the sensory paralysis, without vesical or rectal symptoms, lasted nineteen months and a half.

In closing, the speaker said that Pott's disease in the dorso-lumbar region, as well as confirmed rotary lateral curvature in this same region, might wholly arrest menstruation. He believed this clinical fact had not been noted before, yet he had records of four such cases.

DR. DE FORREST WILLARD of Philadelphia presented skiagraphs of two cases now under his care. He had hoped by their aid to obtain new light on the diagnosis and pathology, but this hope had not been realized. One was of a young boy, and the other of a young girl. There was no improvement in the boy for ten months, and just as he was about considering the advisability of an operation, some improvement was noticed. Now, after eight months, he was well on the road to complete recovery. The girl has been under treatment for only six months, and already a slight improvement had been noted.

After the brilliant results reported by Macewen and Horsley, he had felt that in the more severe cases there was hope of giving relief by surgical interference. His first three or four cases of laminectomy were successful, although not brilliant. Then came two deaths, one from shock, and the other a month after operation. This had led him to look up the statistics, and these had appalled him. He had collected 194 cases of operative interference for the relief of spinal paraplegia. The majority were in children. In four the result was not recorded. Of the 190, then, thirty-five per cent. were recorded as successful, but later reports showed that the symptoms returned in some of the cases. Sixty-five per cent. either died or were not materially improved. One-fourth of the cases operated upon died from shock within the first day or two, over one-third died within one month after operation, and forty-five per cent. died within the year—in other words, for a disease which does not in itself kill, and which is slow in progress, in nearly one-half the cases life appeared to have been positively shortened by operation. Laminectomy, therefore, was an operation which should only be undertaken in decidedly desperate cases. Some years ago he had made it a rule to employ careful mechanical treatment for at least a year before interfering surgically. More recently he had lengthened this period, but still he would not have the patience to wait for six years, as Dr. Shaffer had done. He believed the large majority of these cases were benefited by extension and fixation, at first in the recumbent position. He was also a believer in the administration of iodid of potassium, or of other alteratives, in these cases. Looking back over his thirty years of practice, he could not recall more than two or three cases of spinal paraplegia that were not walking, although, perhaps, not perfectly.

Regarding the technic of the operation, the speaker said that he had tried the U-shaped flap, but he had found that while it preserved the laminæ, it prolonged the operation. In the upper dorsal region the operation is simple; in the lower dorsal and lumbar regions it is exceedingly difficult and tedious. The hemorrhage consequent upon division of a large mass of muscles is very great. He had also noted that handling of the spinal cord was almost immediately followed by a tendency to collapse. He considered the operation justifiable in cases which resist proper mechanical treatment for a year and a half, and which show that the spinal cord is in a condition to transmit motor and sensory impressions; also in cases in which there is both sensory and motor paralysis without improvement.

Dr. Robert Abbe said he had felt for a long time that the cases upon which the surgeon should operate were those which the orthopedic surgeon gave up, and these were very few. The surgeon was reluctant to operate because of the danger of disseminating tuberculosis by the operation. He firmly believed that if nature had an opportunity she would surround the tubercle bacilli with a fibrous barrier which would localize the disease and prevent general infection. This doctrine of avoiding resection of tubercular parts applied with special force to the spine. Simple laminectomy was not especially difficult, although it was followed by great shock. He believed that the U-shaped incision and the free division of the muscles were responsible for much of the hemorrhage and shock. By simply incising along the side of the spine down to the laminæ, no muscles were cut through. The muscles are scraped away from one side, and the laminæ, with attached muscles, are drawn to one side. The laminæ could then be divided without undue hemorrhage. By this method the operation was extremely safe. If there was much handling of the cord there undoubtedly would be great shock. By picking up the dura he had been able to roll the cord to one side so that he could inspect its anterior surface without producing shock. There was, of course, much unavoidable manipulation if one would thoroughly remove the disease and cure the patient. The laminæ are not at all necessary to the support of the spine, but they may be missed if the bodies of the vertebræ are extensively destroyed. Even after primary union, a sinus is apt to form after a short time, owing to imperfect removal of the disease, and this sinus interferes with mechanical appliances.

Dr. Joseph Collins said that he had been taught that one of the most important diagnostic signs of compression paraplegia was an increase of the reflexes, and although this is the rule, yet in his own experience there was in a number of cases absence of knee-jerk and ankle clonus. He had, with Dr. Fraenkel, collected seven specimens of compression myelitis, three of which were cases of Pott's disease, to demonstrate this fact in cases in which a careful clinical history had been secured. This condition of the reflexes is not easily explained, but it seemed to the speaker that the theory propounded by Bastien in 1879 allowed of a more satisfactory interpretation than did any of the others. In fact, the theory founded on the "cut-off" influence existing between the reflex arc and the cerebellum seemed to have the greatest support. The report just made by Dr. Gibney of nearly fifty per cent. of recoveries should be sufficient to show that we had no right to subject the patient to such a hazardous operation as Dr. Willard had shown laminectomy to be. The degree of deformity he had found to have no apparent relation to the extent of the paralysis. He recalled a case in which there was no deformity, although the paralysis was extensive. He had observed the absence of menstruation in one case, and believed he had spoken of this fact before the Orthopedic Section two years before. Iodid of potassium was certainly useful in these cases, yet the use of this remedy, as some believed, to the exclusion of rational mechanical treatment, was to be deplored.

Dr. M. Allen Starr said that from experience with operations on the spinal cord for other conditions, he thought we should be very cautious about meddling with the cord, and that if it had been once damaged it was practically useless to place it in a favorable condition for recovery, as it did not seem to have the power of regeneration. He had been surprised at the remarkable improvement that had occurred in cases of almost total paraplegia as a result of careful mechanical treatment. It should make one careful in the prognosis given in all cases of compression paraplegia. It was very rare for him to see a case in which the tendon reflexes were not very markedly exaggerated, so that his experience did not at all coincide with that of Dr. Collins. The majority of observers, he believed, still continued to find the knee-jerks exaggerated and clonus present when the cord was compressed above the mid-dorsal region.

Dr. C. A. Herter said that the pathological conditions underlying the desperate cases of compression myelitis were such as to give very little hope of anything more than the most temporary relief from operation.

MASSAGE IN THE TREATMENT OF FRACTURES.[1]

BY GEORGE WOOLSEY, M.D.,
OF NEW YORK;
PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE NEW YORK UNIVERSITY; SURGEON TO BELLEVUE HOSPITAL.

UNTIL very recently less advance had been made in the treatment of fractures than in any other department of surgical practice. This is the more remarkable on account of the frequency of this lesion, and it is accounted for by some[2] on the ground of the fear of suit for malpractice if any but the stereotyped methods are employed. As many writers state it can scarcely be denied that the usual method of treatment of fractures is far from giving entire satisfaction, but is regarded as a necessary evil.

Comparatively recently, the "ambulatory treatment" of fractures has received much attention. As to the meaning of the term ambulatory much confusion, it seems to me, exists. What is new in this method is not that the patient is allowed to walk about with crutches after the fractured leg is put up in plaster, but that the plaster is so applied as to act as a combination of an extension splint and an artificial leg, so that the patient walks on the sole of the plaster splint without the support of a crutch or cane. In common with many others I have tried this plan of treatment somewhat extensively in fractures of the leg, and with considerable satisfaction. Its advantages are that it maintains the general condition of the body, and is especially useful in the aged and alcoholic by preventing long confinement in bed. It prevents atrophy of the lower extremities and stiffness of the remoter joints (knee and hip), and it allows a certain class of patients to resume business at an early date. It clears the hospital wards but does not allow a day laborer to work much earlier than the former methods. It does not materially shorten the period of healing. It fails, therefore, to fulfil two requirements at which the improvement in the treatment of fracture should aim, namely, (1) a shortening of the time required for bony union, and (2) an improvement in the functional result when union is obtained.

The crippling of an otherwise healthy person for six weeks is bad enough in itself, but unfortunately this is not all or even the worst part of the usual plan of treatment, for when the splint is removed there is atrophy of the muscles, stiffness of the joints, and disturbance of the circulation; and a period, often longer than six weeks, may be required to obtain a perfect functional result for which a lifetime does not always suffice. It is claimed for massage that it fulfills both of the above requirements, and hence furnishes an improved method for the treatment of fractures. But, as Lucas Championnière, the apostle of this method, says, massage introduces into the treatment of fractures an overturning of our previous notions which it is necessary to justify. It is mobilization, represented by massage, versus immobilization, which since time immemorial has been the primary condition in the treatment of fractures.

Immobilization has been supposed to meet the requirements of the proper treatment of fractures on the ground that it (1) suppresses pain, (2) best permits the restoration of the original form of the member, (3) facilitates the repair of the fractured bone, (4) is the best means for the recovery of the normal function, (5) prevents or cures inflammation.

Championnière[1] attacks these premises seriatim and shows:

1. That only the primary pain, due to the movements of the fractured ends on one another, is suppressed by immobilization, and this not entirely for the latter is not absolute until callus binds the ends together. It, moreover, allows and favors a secondary pain in the neighboring muscles, joints, etc., which is largely due to the swelling from ecchymosis and edema.

2. That the statement that the restoration of the member to its original form is accomplished by immobilization is only relatively true, and especially so in the most important fractures, *i.e.*, at the ends of bones in which consolidation often takes place in a form different from the primitive one. Reduction only corrects the displacement imperfectly in many cases, and the latter may be reproduced by serous or bloody extravasations or by faulty apparatus.

3. That instead of favoring the repair of bone immobilization causes a scantiness of callus. We have all had experience of cases of delayed union in

---

[1] Championnière; "Traitement des fractures par le massage et la mobilization."

which motion is one of the first things we prescribe to induce a healty reparative action, and the formation of sufficient callus. It is said that certain fractures in dogs will not heal with apparatus but only without it, provided that there be not too active motion.

4. That immobilization is the worst instead of the best condition to assure the recovery of normal function. In healthy muscles, ligaments, and joints, forty-eight hours of repose causes a tendency to pain on using, and so much more so if there is serous and bloody extravasation in these parts, following an injury. Immobilization has a bad effect not only on the injured part and its neighborhood, but on remoter parts, and even on the opposite limb in cases of fracture of the leg.

Atrophy of the muscles, stiffness of the joints, want of suppleness of the ligaments and tendons, and disturbance of the circulation, are effects of immobilization with which we are all familiar, and which require time and perseverance to overcome. Although long immobilization does not cause true anchylosis it does cause so much stiffness in a joint, especially in one near a fracture, due to infiltration of the ligaments and tendons, swelling of the synovial membrane and atrophy of the muscles, that the effect is nearly the same. And this effect is the more lasting the older the individual, so that after a certain age one never obtains a complete functional result after treatment of a fracture by immobilization.

5. That inflammation depends upon bacterial infection and not on movement, the danger of which lies in the repetition of the tearing and contusing of the tissues. Immobility only lessens the pain of inflammation.

Championnière adds that the absolutely exact return to the original form of the skeleton after a fracture is not as important as the complete return of the function of the joints, muscles, etc., a position that I think is sound though many may be inclined to question it on the false assumption that perfect position means perfect function after a fracture.

As to massage, the above-named author makes the following statements among others. (1) A certain amount of motion is favorable to the repair of bone. (2) Massage is complex therapeutically; it gives a favorable degree of movement and by many unknown ways causes the repair of bone to be rapid and regular. (3) Certain degrees of deformity contraindicate massage, at least its immediate application.

Movement is life to the soft parts and is necessary to the formation of callus. It assures more rapid and complete repair. Fractures of the clavicle and ribs heal almost invariably and very rapidly, though subjected to constant or frequent motion, and since the stone age fractures have healed in man, the apes, and lower animals, without treatment. Non-union in long bones, not immobilized, when it occurs, is not due to mobility so much as to the want of contact. If a fracture is absolutely fixed the callus may be so scanty as often to cause delayed union. But on the other hand there is a limit to the amount of useful movement, and there are conditions when all movement is contraindicated. The movement in or near a fractured part should be made by the surgeon and not in connection with the function of the part. When made by the surgeon it is useful from the very beginning of the treatment. The only obstacle is pain, but this is overcome by the massage, the principal means employed to provoke the slight movement.

Massage is the best means of causing slight movement without pain at the site of fracture and is, according to Championnière, the fundamental principle of the treatment of fractures. Massage is a broad term, and the particular form applicable to the treatment of fractures should be carefully studied as the discrepancies in results obtained by this method are attributable to the variations in the means employed. Massage should not be of the violent kind such as is often applied in old fractures, or after fractures have united. A surgeon can apply it better than a masseur on account of the preformed habit of the latter of using too much force, and the better knowledge of the complex injury, and of the anatomy of the part, possessed by the former. The index of the massage should be the absence of pain, for pain should not be provoked but relieved by the treatment.

The Effects of Massage.—The first effect as well as the first aim of massage is the disappearance of pain. This effect should be reached without causing pain in the act of massage, and is obtained by gentle, repeated, centripetal movements of the whole hand. Although hard to account for, the relief is probably due to the disappearance of exudation in the distended tissues and to a direct effect on the nerves, which also contributes to the hastening of repair. A second important effect of massage is the diminution of the swelling of the limb caused by the resorption of the ecchymosis and edema which ordinarily increase for the first five days, while if massage is applied daily from the first the swelling has about disappeared by the time it usually begins to subside, although at first between each period of massage the swelling may increase somewhat. Also, the secondary edema which often comes on after five or six weeks, especially in aged patients when the limb is first used, is conspicuous by its absence. This is due to the improved circulation following the early removal of the exudation and the continued massage.

Furthermore, the muscles are kept from atrophy, the joints and tendons from stiffness, the skin is soft and supple, and the return of the part to vital activity is rapid and satisfactory. The patient desires to resume the function of the adjoining articulations and even of the fractured member as soon as the pain has disappeared, and has to be restained rather than encouraged in his desire. The great rapidity of the cure of contused muscles when massaged is well known. In fine, massage favors the perfection as well as the rapidity of repair of all parts.

Practice of Massage.—(1) It may be commenced at once and continued every day, the limb being placed in a removable apparatus or not according to the tendency of the fracture to displacement. (2) After being first massaged the limb may be placed in a plaster splint and massage recommended in a few days, when the splint is removed, to be reapplied and removed daily. This course may be adopted when there is moderate tendency to displacement. (3) When there is great mobility of the fragments, immobilization may be employed, to be followed by massage after the commencement of consolidation. In general, and when it is possible to do so, the earlier the massage is used, and the more systematically it is kept up, the better are the results.

The maneuvers of massage are simple, and consist of a series of movements in the direction of the muscular fibers and blood current, made by the thumb, fingers, or whole hand, making more or less pressure, according as the effect is to be superficial or deep. The thumb, or thumbs, or two fingers, are employed if a deep effect and strong pressure are desired, otherwise the whole hand. First, it is necessary to fix the member to be massaged, and this is done by supporting it on a hard pillow or, better, a sand cushion molded to fit the part; or, later on, by resting it on the knee; or, in the upper extremity, by the weight of the limb. Traction is made by the hand not massaging or by an assistant, in which case both hands may be used to massage, if desired. The best lubricant is olive oil, the next best soapsuds, and perfect cleanliness should be observed. The part should be massaged for from fifteen to thirty minutes once a day, oftener may do more harm than good.

The cardinal rule that the massage should cause no pain is always to be borne in mind. Therefore, at first, very little pressure should be made, and the whole hand should be used, commencing well below and ending far above the fracture, and *omitting all pressure* over the site of the fracture *at all times.* After five or ten minutes, gradually increasing the pressure, a certain degree of anesthesia is produced, and deeper pressure may be made on the muscle groups by using the thumb or two fingers. The energy of the pressure should vary with the age of the fracture and its variety. Other movements, besides the slight ones due to massage, are of themselves painful, hence they should be made, when desired, at the end of massage, when the part is made more or less anesthetic. They may be of two kinds, active and passive. The neighboring joints should be moved by the surgeon and, early in the course of the treatment, the pain having disappeared, the patient may be allowed to make active movements, but these should be limited, as there is more danger of too much than too little, owing to the absence of pain and the general normal feeling of the part. The remoter joints also should not be forgotten in the movements.

In the matter of retentive apparatus between the periods of massage, Championnière is very radical, discarding everything except a flannel bandage, save where there is a tendency to displacement, and even in these cases, as soon as there is a certain degree of consolidation. Of course, in fractures with any *marked* tendency to displacement, retentive apparatus must be employed until this tendency disappears with beginning consolidation.

Contraindications.—Certain conditions, besides extreme mobility of the fragments, contraindicate massage for a time, namely, large or numerous blebs, until they are dried up; also, a sharp fragment threatening to perforate the skin, or open vessels. On the other hand, compound fractures, especially those compounded from within by a sharp fragment, may be massaged at a comparatively early period when the usually small opening has closed.

The practical results of the treatment of fractures by massage may be summed up as consisting of (1) the disappearance of pain (as in the similar treatment of sprains); (2) the disappearance of tension and swelling in the tissues from the absorption of ecchymosis and serous effusion; (3) the sedative nervous effect; (4) the extreme rapidity of the formation and consolidation of callus; (5) the early establishment of function; (6) the absence of atrophy of muscles, stiffness of joints and tendons, secondary swelling and edema, and poor circulation. In short, a very rapid recovery, marked by comparative absence of pain, and an excellent functional result.

It is in fractures at the ends of bones that the results of this treatment are the most strikingly good, and those of immobilization the worst. In such fractures the deformity is less and the vascularity greater, so that, though extravasations are common and extensive, their resorption by the use of massage is very rapid and complete. In Championnière's hospital service the average duration of the treatment of fractures of the fibula is three weeks, and patients with fracture of the radius commence to use the hand in eight days. In other fractures the time of treatment is proportionally shortened, and not only this, but the functional result is most excellent. The foregoing is a brief summary of Championnière's views and practice, which are fully detailed in his book.

Admitting that, in advocating a new plan of treatment, the pendulum only too often swings too far, and that the best and safest plan is to be found somewhere midway, we may ask the question: What have others to say of the use of massage in the treatment of fractures, and what has experience taught us? French and German medical literature contains numerous references to this plan of treatment, indicating its extensive trial abroad. The practice of most German surgeons is not so extreme as that of Championnière.

As both P. Klemm[1] and Bum[2] say, the fractured bone demands rest, but muscle and joints bear it badly, and demand movement. Accordingly, the two last named surgeons limit its application to fractures in or near joints in which, as Klemm says, all agree that long-continued immobilization gives very questionable results. According to Klemm, the extravasation of blood in and about the joint is the essential factor in the loss of function of the joint, which is the serious part of these fractures. Some of this blood is absorbed, but most of it is changed to a connective-tissue thickening of the synovial membrane, causing contracture and adhesions. The extra-articular extravasation also affects the function by making the ligaments and tendons stiff. If this process is once under way the function of the joint is doomed, and it may always be crippled by it. Even the monarticular form of arthritis deformans has been shown by Volkmann to occur after such injuries. The treatment of such fractures must eliminate the extravasated blood, and this indication is fulfilled by massage, which meets another requirement by preventing muscular atrophy.

Movement of the joints is added to prevent stiffness and contracture. It is an essential feature of this method, according to Landerer,[3] that the soft parts receive as much attention as the formation of callus, for atrophy of muscles is marked after twelve days of disuse. Furthermore, Landerer and Bum, in accord with Championnière, point out that early massage, by improving the circulation, favors and hastens callus formation.

The carrying out of the treatment by massage is subject to considerable individual variation among surgeons who have reported their experiences.

As callus formation commences almost immediately, and does not delay until the fourth or fifth day, as was formerly supposed, crepitus until then being due to bony spicules, which are absorbed after about the fifth day, Landerer insists that fractures should be put up at once in the best possible position. Like Klemm and Bum, he does not like massage continuously from the first for fear of the displacement of the fragments and the misformation of callus, especially as no time is thereby gained. He makes one exception to this in impacted fractures which it is impossible to reduce, and he also states rather ambiguously, that joint fractures cannot be treated too soon by massage, passive motion and change of position of the splint. Accordingly, the above-named surgeons treat fractures near joints as follows: After careful reposition of the fragments, if necessary, and with or without being first massaged, the limb is put up in a plaster or other form of splint. After from four to twelve days, varying according to the nature and position of the fracture and the practice of the individual surgeon, the splint is removed, the limb massaged and again applied in the splint, and the massage repeated every day thereafter with passive motion in the neighboring joints. The results of this practice appear to be excellent. For instance, in malleolar fractures, the patients walk with two canes after fourteen days and in three weeks without any support (except, perhaps, in going up stairs). In twenty-eight cases of fracture of both malleoli in Klemm's practice, the average length of treatment was 24.3 days, and in thirteen cases of fracture of one malleolus 18.6 days. According to Lumniczer's[1] table, in fractures treated by massage and movement bony union was obtained in one-third and a functional result in one-half or two-thirds shorter time than when treated by immobilization. Collé's fractures are cured in even shorter time than malleolar, free use of the joint being obtained in fourteen days.

A further argument for the treatment by massage and passive motion of fractures near joints is found in the fact that this treatment is so generally and successfully applied to sprains. We may add that, according to Landerer, ninety-five per cent. of so-called sprains of the ankle are really fractures, and ninety-nine per cent. of sprains of the wrist are fractures of the lower end of the radius.

As above indicated, German surgeons do not consider fractures of the shaft of bones applicable to treatment by massage, on account of the tendency to displacement, until after consolidation by callus or except where there is no tendency to displacement, or where a little over-riding would cause no loss of function, as in fracture of the fibula. Otherwise in fractures of the shaft Burn would immobilize for ten to twenty days, until callus formation is assured. According to Landerer also all oblique fractures must be treated by extension where both bones or the only bone of a limb is broken. Klemm would recommend for fractures of the shaft of the bones of the leg Krause's ambulant treatment, in which, for about eight days, massage is employed daily with elastic compression between times. In eight days the swelling has subsided and the ambulant splint applied. This combines some of the advantages of both methods, but by no means all, and it has seemed to me that these advantages might be well combined in fractures near joints. But in the latter class of fractures Krause's method is faulty, for it exposes the joint to the dangers of stiffness from immobilization after the eighth day. This was strongly impressed upon me by two of my cases in which massage was being applied, and which I put up in plaster after a week or so on account of the marked deformity of the Potts' fracture, being uncertain of the results of the massage method in such cases. Before the plaster was applied the ankle was freely movable and the site of the fracture painless. After two weeks in plaster the ankle was stiff and painful on motion, and the position, though good, was no better, if even as good as in a similar case massaged throughout.

A combination of the advantages of the ambulatory and massage treatment can, I think, be obtained, in a measure at least, by the method suggested by Dollinger[1] or modified to the extent that the walking plaster splint is cut down in front instead of on both sides, as he suggests. In either case the splint is held securely in place by three or four broad straps. Of this modified method I made a partial trial in one case, with the result that it seems to me to be feasible. There is one fracture, preëminently a fracture near a joint, in which the poor functional results often obtained are due largely to two causes—the changes in the blood in and about the joint and the atrophy of muscles, both of which are remedial by massage. I refer to fractures of the patella. Burn's remark that every method of treatment of these fractures which results in bony union leads to important loss of function, deserves careful consideration.

The facts justify Klemm's statement that bony union seems to be the primary object of many, the functional result secondary. All will admit it to be true, as Landerer says, that the great need in the treatment of fractures of the patella is a method that every one can apply. Such a method I think we have in one of the various modifications of the application of massage. This does not seek to obtain bony union, but, when the distance between the fragments is not too great, anatomical restitution of the parts is not necessary.

I do not wish to be understood as opposing operation in cases of fracture of the patella. I have frequently operated myself and expect to continue to do so in suitable cases. The treatment by operation should be confined, however, to surgeons who can operate with every facility. It remains true, however, that a large number of such fractures must be treated by others, and the need of a method giving a good functional result is met by the massage method with the additional advantage that the duration of treatment is much shortened. As to the ambulatory treatment, Landerer and Klemm agree that it is just the thing in cases of fracture of the neck of the femur in old people, and that this is about the only fracture near a joint where it is called for. Klemm adds that such injuries are satisfactorily treated in this way by the use of a Thomas' splint in A. von Bergmann's wards in Riga. I would certainly add all fractures of the leg, especially of the shaft of the bones, in old people and alcoholics to the list of those to be treated by the ambulatory method, or, preferably, this method combined with massage.

Treatment by massage is indicated in all fractures in or near any joint as well as those especially referred to. Thus Selenkow[1] reports a case of fracture and dislocation at the elbow in which massage was employed with great success, active motion being begun in fourteen days and the splints removed in seventeen days.

With many of the above facts in mind, my own experience, by no means extensive, commenced rather cautiously somewhat over a year ago. I have for the most part only treated fractures near joints, in which the method seemed to me to meet an urgent need. The fractures so treated have been mostly Potts' fractures, and the treatment has been carried out mainly by the house staff or nurses of the First Surgical Division of Bellevue Hospital. Up to the present time I have treated thirteen Potts' fractures, and three are now under treatment. Of these cases four were treated a year ago, the rest during the present winter. I have also treated, or have under treatment, fractures of the radius (Colles'), elbow, patella, shoulder, and leg. I have, perhaps, been over cautious at first, and have not allowed the patients to get up quite as early as the French and German surgeons, whose results I have reported. Furthermore, I have not hesitated, if the position seemed to be faulty, to suspend massage and put the leg up in plaster to correct displacement. In such cases the difference between the two methods has been made very striking. The ankle joint, comparatively supple when put up in plaster, has been decidedly stiff when the plaster was removed ten or fourteen days later. As stated above, this led me to the idea of combining the advantages of the ambulatory and massage methods advocated by Dollinger. I have only had enough experience with this plan to determine to test it more thoroughly and to venture the opinion that it promises an ideal method of treating periarticular fractures of the leg. The deformity of a Potts' fracture may be corrected by applying between the periods of massage half of a plaster cast applied in the correct position of the limb. Otherwise I have used for the most part a Volkmann's splint to retain the leg between times for the first fourteen days.

[1] T. A. Selenkow: "Zur Behandlung der Fractura Simplex."—*St. Petersburg Med. Wochenschrift*, 1889, No. 6.

As to the results of the treatment by massage, my experience has been very encouraging, so much so that I have made it the routine treatment in my wards in Bellevue Hospital in fractures near a joint. Pain and swelling subside early, and the patients often express a desire to get up before I allow it. Bony union is obtained by the end of the third week, and when I let the patients get up (from the nineteenth to the twenty-fifth day) they are able to walk without a cane within two or three days with little or no stiffness or pain.

As far as my limited experience justifies me I can conscientiously recommend the method to others, for it is easy of application, though demanding somewhat more time on the part of the surgeon. The time from the receipt of fracture to the commencement of massage has varied from 1 to 8 days, and has averaged 2 days. Massage was applied, as a rule, once daily for fifteen to twenty minutes, followed by passive motion which increases with the time after the fracture. The time from the receipt of fracture to the first time allowed up has varied from 18 to 27 days, and averaged 22.3 days; and to the time when the patient could walk without any support has varied from 21 to 32 days, and averaged 27.5 days. The average stay in hospital has been 31.3 days (*i.e.*, from 18 to 41 days). One patient, a woman who weighed 200 pounds, with a bimalleolar fracture, walked without support, and without pain and stiffness, in 21 days. That the result in each case has not been proportionately good is not surprising considering that massage has been applied by a number of different persons not equally skillful. In fact, the method has not yet been used enough to educate any one of those giving the massage to a high degree of skill in its use. Hence, the method has been tried under disadvantages, and it is not strange that in three cases we have applied plaster splints after varying periods of massage. The results in these three cases, showing almost the same degree of joint stiffness as in cases treated by immobilization, has impressed upon me the importance of applying the massage last,' the plaster first. Partly for this reason, partly because the recent cases of Potts' fracture have had extreme mobility and deformity, and partly to try the plan of massage treatment practised by the German surgeons referred to, I have adopted of late the latter method and put the fractures up in plaster at once for a variable time, and then applied massage and passive motion, keeping the limb between times in a part of the plaster splint. I have done this the more readily because I believe that the treatment of fractures near joints by massage is especially adapted to private practice, where we are held more personally responsible for the functional result, and where the surgeon as well as the patient might hesitate to be without the security of a plaster splint at first to maintain the parts in the best position.

The following conclusions may, I think, be drawn from the consideration of the above:

1. The treatment of fractures, especially those near joints, by immobilization, whether ambulatory or not, leaves something to be desired in (*a*) the time required and (*b*) the functional result obtained.

2. The treatment of such fractures by massage and passive motion shortens the time of bony union by one-third or one-half, and vastly improves the immediate functional result.

3. This treatment is especially applicable and important in fractures near joints.

4. Its application is easy. It relieves pain and swelling, hastens callus formation and solidification, prevents atrophy of the muscles and stiffness of the joints and tendons.

5. Splints should be applied between the daily fifteen or twenty-minute applications of massage for the first ten or twenty days, according to the nature of the fracture and the tendency to displacement, or until consolidation occurs.

6. This treatment, combined with the ambulatory method, promises an ideal method.

7. Oblique fractures of both or the only bone in a limb, or fractures near the middle of the limb with a tendency to displacement, should be immobilized until consolidation has commenced.

8. The ambulatory treatment is indicated in the latter classes of fractures, in fractures of the lower extremity in the alcoholic or very aged, and in fractures of the neck of the femur in the aged.

9. The plan of immobilizing the limb for a short time in the best possible position, and then applying massage and passive motion, promises equally good results, and especially adapts the method to private practice in which it is particularly indicated on account of the shortened time required for union and the excellent functional results.

OPIUM POISONING.

By CARL JOHNSON, M.D.,
OF DENVER, COL.;
LECTURER ON GYNECOLOGY AT THE DENVER UNIVERSITY MEDICAL COLLEGE.

IN A paper on "Suicides" which I read before the Denver and Arapahoe County Medical Society in February, 1894, I reported twenty-eight cases of poisoning by opium. I have since then treated twenty-seven additional cases, making a total of fifty-five, eight of which proved fatal. One patient died just as I arrived. The other seven lived from one to twelve hours after treatment was commenced, except one man, mentioned in my former paper, who died from inanition after ten days had elapsed. Thirty-nine took morphin, thirteen laudanum, one aqueous extract of opium, and one gum opium. The drug was taken by the mouth in all but two instances. In one of these a young man allowed a woman who was addicted to the use of morphin to give him two hypodermic injections of the drug, each of about one-third of a grain, "just to be sociable," to use her own expression. The other patient smoked opium, and followed it up by taking a large dose of opium internally. The amount taken by the various patients varied from one grain to one dram of morphin, and from half an ounce to three ounces of laudanum. Thirty-five patients were already so far under the influence of the drug when first seen as to necessitate the use of the stomach pump for the evacuation of the stomach. The remainder were seen early enough for emetics to be of service.

The symptoms caused by opium when taken in poisonous doses may be divided into three stages: First, that of increased nervous excitability; second, a condition of somnolence or drowsiness; third, the stage of narcosis. The duration of the first two stages varies greatly in different cases. When a very large dose is taken, the first may be entirely absent, or may last only a few minutes. The patient in this stage acts not unlike a man partially intoxicated. The heart's action is increased, the face is flushed, and the imaginative powers are increased. If the case is one of attempted suicide, the patient often tells, while in this condition, what he has taken. The second stage is of short duration if the dose has been a large one, its length increasing as the dose is diminished. If but little more than the medicinal dose has been taken, this stage lasts for several hours, and is followed by a return to consciousness. The condition at this time very closely resembles sound sleep. The respiration and pulse are normal, or nearly so, and the pupils are contracted. The patient, when aroused, is often annoyed by a violent itching of the skin, sometimes general, but more often confined to the face, especially the nose.

In the third stage, opium poisoning is sometimes differentiated with great difficulty from uremic coma, alcoholic narcosis, cerebral hemorrhage, and the condition following an epileptic convulsion. In uremic coma the pupils are usually normal or dilated, but may be contracted; convulsions generally occur, and anasarca is usually present. The urine is always loaded with albumin, and the temperature is said to be always below normal. In alcoholic narcosis the pupils are normal or dilated, the respirations are not as slow as in opium poisoning, and the pulse is slow and full. Too much dependence must not be placed upon the odor of alcohol, as the patient may have taken opium while intoxicated. A hypodermic injection of apomorphin will cause a man unconscious from alcohol to vomit, but will have no effect if the case be one of opium poisoning. In case of cerebral hemorrhage there is usually more or less paralysis of the cranial nerves, with some differences in the reflexes of the two sides of the body, and in the size of the two pupils. In the coma following an epileptic convulsion, the tongue will probably be bitten, the pupils dilated, and the respirations but little slower than normal. The history and surroundings are often more valuable aids to diagnosis than the physical condition. The occurrence of a convulsion at the beginning of the attack will exclude opium poisoning, although it may occur in any one of the other conditions named.

The prognosis in the first and second stages is usually good. In the third stage it is uncertain. Drunkards recover poorly, and the prognosis should be guarded when a drunken man takes opium, even when there is only slight absorption before the case is seen.

There are two objects to be attained in treatment. First, to remove or render harmless the opium still remaining in the stomach; and second, to support the vital functions until the poison has been eliminated from the system, or, if possible, destroy it in the blood without waiting for the slow process of elimination.

The first of these indications can be met by emetics, the stomach pump, or by permanganate of potash. Of the emetics, apomorphin is probably the best, because the quickest. One-tenth of a grain should be given hypodermically if the case is in the first or second stage. It should never be given in the third stage, as it will not produce emesis after unconsciousness has supervened, and may cause dangerous heart-depression. In fact, I am inclined to believe that it has helped to cause a fatal result in some of my cases in this way. It will, however, act at a later stage of opium narcosis than any other emetic with which I am acquainted, so if an emetic is to be given at all I prefer the apomorphin. It is better to risk its bad effect on the heart than to fail entirely in producing emesis, unless a stomach pump is at hand. When a pump is available it should be used instead of an emetic if a patient is nearing the third stage, or, in other words, when he can only be aroused with difficulty.

Although the apomorphin produces no effort at vomiting when administered to an entirely unconscious patient it seems to depress the heart even more than when given to a partially conscious person. When the pump is used, the stomach should be filled with warm water and repeatedly emptied until the water is returned clear. The stomach should then be filled with hot, strong coffee. When apomorphin is to be given, the patient should be induced to drink as much water as possible while the hypodermic syringe is being prepared. If this is postponed until after the injection is given, nausea sometimes comes on so quickly that it is hard to induce the patient to drink a sufficient quantity to liquefy the contents of the stomach.

After the unabsorbed opium has been removed by the emetic or stomach pump, the respiration and circulation should be kept up by stimulants, of which there is a considerable number in use. I place the greatest reliance in strychnin, giving it in the form of the sulphate in doses of $\frac{1}{25}$ of a grain hypodermically as often as the respiration or pulse becomes weak. Atropin I consider useless, and I no longer use it except when it becomes necessary to do so to avoid censure from other physicians. Digitalis is of undoubted value when the pulse is weak. Aromatic spirits of ammonia acts nicely, especially when there is sudden failure of the heart's action. The inflammation which often follows its injection makes its use objectionable. I am undecided as to the merits of nitroglycerin. I do not favor the external use of cold water for the purpose of keeping the patient awake, as it is too depressing. Beating or abusing a person for this purpose is also unjustifiable. The faradic current applied to the face and neck is much more efficient and leaves no bad effects. In many cases of opium poisoning, death has undoubtedly been due to the shock and exhaustion caused by the long-continued beating and forced walking to which the patient has been subjected by the well-meaning but misguided attendants.

The beneficial effects of the faradic current is no doubt due principally to the fact that it causes pain, or at least an unpleasant sensation, and thereby keeps the patient aroused. The current should therefore be strong enough to be decidedly unpleasant, and metal electrodes should be used. If a faradic battery is not obtainable, the next best thing is to keep the patient aroused by talking to him, pulling his nose, slapping him lightly, and similar procedures. Under no circumstances should he be dragged around the room between two men or severely beaten. Cases which recover under that style of treatment recover in spite of it, and not on account of it. The galvanic current, when available, is of undoubted benefit in stimulating respiration.

I have tried dilatation of the anal sphincter. It is of no more benefit than any other procedure which causes an equal amount of pain, and I think it unjustifiable. I hold the same opinion in regard to the rectal injection of irritating substances such as tincture of capsicum.

In the New York *Medical Record* of February 17, 1894, Dr. Moor published an article advocating the use of permanganate of potash as an antidote to morphin. He had taken as much as two grains of sulphate of morphin, followed by the same amount of permanganate, without feeling any effects from the dose. The remedy became famous in a day, although at that time it had not been tried except in the experimental way mentioned. Since then a considerable number of cases have been treated with this agent and reported, and a great deal of discussion has taken place in regard to its action. In all the cases I have been able to find reported, the usual remedies have also been used, and the result of the entire treatment has been about what I would expect without the use of the permanganate.

In another article by Dr. Moor on the subject, published in the MEDICAL NEWS of May 4, 1895, he makes the following bold statement: "I say that any physician on arriving at the side of a person suffering from opium poisoning, who does not at once administer to that person a sufficient quantity of the permanganate, commits an act of gross negligence." He then goes on to state three different indications for the use of the drug. The first is to neutralize any opium which may remain in the stomach. This is effected by giving a sufficient quantity of the permanganate internally, well diluted. He allows one grain for each grain of morphin which has been taken. If the patient is sufficiently conscious to swallow, and the permanganate is certain to render the opium harmless, and I believe it is, this treatment does away with the danger of heart depression, which I have already mentioned as sometimes following the use of apomorphin.

The second indication, as given by Dr. Moor, is to destroy the morphin contained in the circulating blood through hypodermic injections of the antidote. That sounds very nice in theory, but I have put it into practice with disastrous results. I was called to see a man who had taken a large dose of morphin. The quantity could not be ascertained, neither could the time at which it had been taken, but he could not be aroused in the slightest degree. The respirations were four to the minute, and the pulse was weak and rapid. His stomach was emptied and thoroughly washed out, and then filled with hot coffee, and my usual treatment was carried out. At the end of two hours he was sufficiently recovered to fight vigorously when the faradic current was applied to his face. He spoke and nodded his head in answer to questions several times, and vomited the coffee which had distended his stomach. This case occurred soon after the permanganate treatment was first announced, and I had not as yet had an opportunity to try it. I had provided myself with a two-per-cent. solution, and, as the case now seemed in a fair way to recover, I decided to hasten the recovery by "destroying the morphin which was still in the circulating blood," to use Dr. Moor's expression. At intervals of about five minutes I gave hypodermic injections of the two-per-cent. solution, giving ten minims at each injection, until I had given 100 minims, which would equal two grains of the drug. The patient had by this time relapsed into insensibility, the pulse was very weak and rapid, and the respiration shallow. Happening to notice that the skin was very warm, I took the temperature, and was surprised to find it 102½° F. in the axilla. It went up steadily to 103°, 104°, 105°, and 106° F., reaching the latter point before death, which occurred about five hours later. The treatment after the permanganate was used consisted of hypodermic injections of strychnin and digitalin. No autopsy was held.

In another case where a woman had taken two ounces of laudanum, I repeated the experiment with a smaller amount, giving sixty minims of a two-per-cent. solution hypodermically after evacuating the stomach by the use of apomorphin. The woman was sleepy, but was at no time unconscious, and I did not consider her condition serious, as I had been called a few minutes after the dose was taken. Ten minutes after the permanganate was injected the temperature was 100½° F., in thirty minutes it was 101°, in forty minutes 100¾°, and it then went down, being normal eight hours later. On the following day there was again some temperature, due no doubt to the inflammation which had occurred at the site of each of the three injections. In two other cases in which I used the drug hypodermically I failed to take the temperature. Both patients were seen before the second stage was fairly ushered in, and both recovered, as I have no doubt they would have done without the permanganate, and so far as I could judge, the course of the cases was not modified by its use. In every case, except the fatal one, there was considerable local inflammation following its injection.

The third of Dr. Moor's indications is to decompose the alkaloid that returns from the circulation to the stomach. To accomplish this, he advises giving from time to time a tumblerful of a weak solution internally. When a permanganate solution is allowed to remain in the stomach a few minutes and is then withdrawn, it has lost its characteristic color and also its deoxydizing power, just as it does when a few drops of acetic acid are added to the solution. After the stomach is repeatedly washed with a solution of two grains to the pint, the fluid returns unchanged. The conclusion I draw from this is, that to have the permanganate retained in an active condition it is necessary to wash the stomach out with it often enough to temporarily stop the acid secretions from the mucous membrane of the stomach. When this is accomplished, the elimination of morphin from the blood by the stomach is necessarily also stopped. Therefore, if given in large quantities, it stops one important channel by which the poison is eliminated from the blood, and is useless if given in small quantities.

My position in the use of permanganate, stated briefly, is as follows: Taken internally, it renders harmless opium which still remains in the stomach. It is useless or injurious when given hypodermically. It is useless or injurious when given internally for the purpose of decomposing the opium which may return to the stomach through the circulation.

Bellevue Hospital Medical College.—The officers of Bellevue have secured a plot of ground on the corner of First avenue and Twenty-sixth street, 100x150 feet, adjoining the Carnegie Laboratory. Upon this site they propose to erect a modern and substantial structure. The work will begin immediately, and the building will be ready for occupancy on September 1st.

THE PHYSIOLOGICAL ACTION AND THERAPEUTIC USES OF YEAST NUCLEINIC ACID, WITH SPECIAL REFERENCE TO ITS EMPLOYMENT IN TUBERCULOSIS.

BY VICTOR C. VAUGHAN, PH.D., M.D.,
OF ANN ARBOR, MICH.;
PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN, AND DIRECTOR OF THE HYGIENIC LABORATORY.

(Continued from page 332.)

CASE XXIX.—J. B., of LaPorte, Ind., came to me in October, 1894. There was no family history of tuberculosis, or known source of contagion. This patient, aged twenty, is under size and weight, his greatest weight having been 118; weight at time of beginning treatment 113. He began to have continued sore throat and hacking cough three years ago, but had been coughing up phlegm only during last two months. There were crepitant râles over apex and subclavicular area on right side. There was a small cavity between second and third rib on right side. The right lung showed general dulness on percussion. The left lung showed no abnormality. The amount of sputum was not more than two ounces in twenty-four hours, but it was rich in tubercle bacilli. There were no night sweats, and the afternoon temperature seldom exceeded 100° F. This patient improved rapidly. By January 1, 1895, the cough had ceased, the temperature was constantly normal, and the weight had reached a few pounds above the maximum. From this time to first of March, 1895, injections were made two or three times weekly. In March, 1895, the only evidence of disease in the lung was some dulness and prolongation of expiratory sound on the right side. However, an interesting bit of the history of this case follows: As has been stated, the cough ceased by January 1, 1895. In August of the same year, the young man coughed up a few mouthfuls of sputum and sent this to me. It contained a few tubercle bacilli. The cough did not continue. From October 1, 1895, to January, 1896, this patient had from two to three injections per week. By June the cough had stopped, and he felt so well that he discontinued the treatment. From June, 1896, to August 1, of same year, this patient had from two to three injections per week, as a precautionary measure. Since August 1, he has had no treatment. He now (October, 1896,) weighs eight pounds more than ever before and has no cough. Examined his lungs carefully October 22, 1896. A very slight prolongation of the expiratory sound over the right apex is the only evidence of abnormality.

This case is of especial interest inasmuch as it demonstrates that apparent cures do not always mean the complete destruction of the bacilli in the body.

CASE XXX.—C. F., of Ypsilanti, Mich., a boy of seventeen, had numerous small cavities in both upper lobes when I first saw him in November, 1894. The treatment was given until February 1, 1895, when the patient was sent to Colorado. The first month of treatment seemed beneficial, but after that the disease progressed. In Colorado he had influenza and came home after four months and soon died.

CASE XXXI.—Miss A., aged twenty-six, of Saginaw, Mich., had bronchial breathing over both upper lobes. Consumption had been diagnosed two years before, and she had spent the preceding winter in the Adirondacks. She had treatment, beginning in November, 1894, and continued for six months. She gained in weight, and coughed and raised less. The bacilli continued in the sputum and the physical signs showed but little change. I have not seen her since she discontinued the treatment.

CASE XXXII.—Mrs. D., a colored woman, aged forty-two, living in great poverty, came under treatment in November, 1894. It was difficult to get any satisfactory family history. "Father died of chronic inflammation of the lungs, and one brother who was sick for a long while, died of pneumonia." She had been with both her father and brother in their last illness. Her bad cold had begun about one year before. During this time she had lost in weight, from 140 to 119 pounds. She coughed and raised profusely, and the sputum was rich in bacilli and in elastic tissue. There was a cavity in the right upper lobe and bronchial breathing on both sides. Treatment was continued as long as the patient was able to come to the office, which was about two months. The disease rapidly progressed and there was no evidence of any beneficial effect of the nuclein. Death occurred a few months later.

CASE XXXIII.—J. H., of Yale, Mich., aged thirty-four. His mother died of consumption at the age of fifty-six, three years ago. He was her principal attendant during her last illness. In January, 1894, he began to cough, and could not speak above a whisper. He had been coughing ever since, and had lost thirty pounds in weight, when I first saw him, which was in December, 1894. He had a large cavity in the right lung, bronchial breathing over the left lung, and tubercular laryngitis. He remained under treatment for three months. During the first six weeks he improved in flesh, gaining nearly fourteen pounds in weight. His throat was treated with a spray consisting of equal volumes of the one-per-cent. solution of nucleinic acid and a saturated solution of boric acid. The condition of the larynx was much improved and the voice regained. However, during the latter half of his stay here, the condition of his lungs grew worse, and after going home he rapidly failed. The improvement was only temporary and, as stated above, the disease progressed while the treatment was being continued.

CASE XXXIV.—Miss B., aged seventeen, came to me December 4, 1894. She had tuberculosis of the right elbow-joint, which had been inflamed and painful for three years. This had been called rheumatism. The joint was discharging at the time of the first examination, and tubercle bacilli were found in this discharge. There was prolonged expiration over both apices, but no cough and no expectoration. There was a purulent discharge from the umbilicus. The afternoon temperature ranged from 100° to 101° F. The one-per-cent. solution of nucleinic acid was injected into the tissue about the joint and the sore was dressed with iodoform gauze. The nuclein was also injected for a few weeks about the umbilicus. The patient at that time remained under treatment until the first of July, 1895. Within six weeks after beginning the treatment, the temperature became normal, and has so remained, with one exception to be mentioned. By the first of June, 1895, the joint had so far improved that the young woman could use the hand in playing on the piano, could feed herself with the right hand and could use the arm in dancing. The discharge had ceased, the wound healed, and further treatment was considered unnecessary. This favorable condition continued until February, 1896, when the joint received two bad blows. Once it was struck with considerable force on the tire of a carriage wheel, and the second time the patient fell on the ice striking on that elbow. March 24, 1896, she returned with a swollen joint and a temperature of 100° F. Dr. Nancrede made an incision, and with a curette removed some tubercular matter. The arm has been carried in an aluminum splint since that time, and the wound washed out daily with the one-per-cent. solution of nucleinic acid. The five-per-cent. solution has been administered by the mouth in teaspoonful doses three times a day. Her general health remains good, and there is no abnormality detectable in the lungs.

[March, 1897. The wound has healed and the general health of the patient is excellent.]

I may call attention in this connection to the favorable reports made by Hitchcock[1] on nuclein in a case of hip-joint disease.

CASE XXXV.—S. M., aged twenty-seven, of Bedford, Mich., was sent to me February 22, 1895, by Dr. G. W. Lowry of Hastings. His wife died of consumption August 8, 1894, after an illness of one year. The husband took care of her during this sickness. About three weeks before her death he began to have a sensation of great weariness and some elevation of temperature. At the time of the first examination, the only physical evidence of the disease was a marked retraction of the left apex and a prolongation of the expiratory sound over this region and the subjacent area. He coughed very rarely in the morning and then raised some sputum, in which a few bacilli were found. The loss in weight had been about ten pounds. The afternoon temperature ranged from 99° to 100° F. After four weeks of treatment the normal weight was regained, the cough ceased entirely and the patient has remained apparently in perfect health since.

CASE XXXVI.—E. A. R., a farmer, aged fifty-four, from Covert, Mich., came to me in November, 1894. His mother died of consumption many years ago. He was not with her in this illness. His mother's sister also died of consumption. One of his own sisters had been an invalid for fifteen years from a fall, and coughed much before her death. Another sister had died some seven years before of quick consumption. He had occasionally visited these sisters during their illness. Five years ago he had a hemorrhage, "followed by pneumonia." In 1890 he had a severe hemorrhage. From the time of the first hemorrhage, in 1889, he had not been well and had steadily lost flesh. In 1893 he had another hemorrhage, and still another about one month before he came to me. He was coughing and raising freely. The sputum contained numerous bacilli and some elastic tissue. His greatest weight had been 175, and at the time of the examination it was 152 pounds. There were numerous small cavities in the upper lobes. This patient remained with me only four weeks, but continued the treatment with Dr. Carnes, of South Haven. Dr. Carnes wrote me under date of March 1, 1895, as follows: "Mr. R. has been under the nuclein treatment now for three months, in addition to the one month spent with you. He now weighs four-and-a-half pounds more than he did at Christmas. His temperature is practically normal all the time, seldom reaching 99° F. However, he coughs much, a clear, ringing cough, without much expectoration. He never before had a three-months' rest, and this has probably contributed to his gain."

A second report from Dr. Carnes under date of November 22, 1895, states: "He coughs much, and says that he cannot endure hard work, but it is plain to see that he is in better flesh and far more vigorous than he was last spring. He has for several years vacillated in this way, so I can see but little difference between the last year and several preceding years."

Recently (October 24, 1896,) Dr. Carnes wrote that this patient, who has had no nuclein now for more than a year, is gradually, but slowly failing in health.

CASE XXXVII.—Miss K., aged thirty-one, of Marinette, Wis., came to me for treatment in January, 1895. There was no known tuberculosis in the family, nor was there any discoverable direct exposure to the contagion. The patient had always been rather frail, her greatest weight having been 120 pounds. However, she had never been ill, until three years before, when she developed a "chronic bronchitis," accompanied by constant cough and profuse expectoration. Sixteen months before coming to me she had gone to Oregon, where she spent a winter, during which she gained thirteen pounds in weight and felt much improved, but even before her return home she began to fail again. Her appetite was very poor and her tongue heavily coated. The sputum contained numerous bacilli and much elastic tissue. There was bronchial breathing over the whole area of both upper lobes. There were numerous small cavities in the same region. The patient remained under my treatment until June, 1895, when she returned to her home, and the nuclein treatment was continued by Dr. Hicks of Menominee, Mich. The result of the treatment was the same in this case as it has been in all others of the same class. There was temporary improvement, with increase in weight, reaching and even passing the previous maximum, and then retrogression, notwithstanding the continued employment of the nuclein.

---

[1] *American Lancet*, January, 1895.

CASE XXXVIII.—Mrs. Q., aged thirty-two, of Gaylord, Mich., was brought to me in January, 1895. I say that she was "brought" to the office, and this is literally true. She was in the last stages of consumption, and after an examination, in which I found numerous cavities in both lungs, I advised her husband to take her home as soon as possible. However, he thought that an immediate return would discourage her so greatly that he insisted on a trial of the remedy for nothing more than its mental effect. This case illustrates what hope and nuclein, probably as much should be attributed to the former as to the latter, may do in the way of temporary improvement. This lady insisted on having full doses every day, and they were given. When I state that she gained twenty-five pounds in five weeks I expect to tax the confidence of the reader in my statements to the utmost; but such was the case. Her afternoon temperature fell from an average of 102° F. to less than 100°, and while she had to be brought in her husband's arms from the carriage into the office when she first came, before she left the city she walked many blocks at a time without feeling great fatigue. At the end of five weeks she insisted that she was practically well, and desired to go home. Believing that the arrest of the progress of the disease was only temporary, I made no objection. She returned home, soon lost what she had gained, and died in September, 1895. I desire it distinctly understood that I do not attribute this great temporary improvement wholly to nuclein. It was one of those phenomenal cases of temporary improvement in which the bacillus seems for a time to have lost its virulence, and the vitality of the patient seems to spring into increased vigor at a bound. The nuclein was not used after she left, but I know that even had its employment been continued the relapse would have come with equal certainty.

CASE XXXIX.—M. G., a student, aged twenty-four, came to me in February, 1895, on account of a slight pulmonary hemorrhage which he had at that time. He was coughing up blood. This was examined and found to contain tubercle bacilli. Treatment was begun immediately and continued for two months. On the first examination moist râles were heard over the apex and subclavicular area of the left lung. The afternoon temperature frequently reached 101° F. for two weeks. After this it gradually fell to the normal. The young man continued his studies until June, 1895, when a physical examination failed to reveal any abnormality. He spent the winter of '95 and '96 in Colorado as a precautionary measure, and there has been no evidence of any disease since the treatment was discontinued.

CASE XL.—W. S., a stone cutter from Bluffton, O., came in February, 1895. This case is almost a duplicate of the one just described and several others of a similar character will be mentioned later. A brother-in-law of this man had died of consumption in his house, after a long illness, some months before. S. had a hemorrhage and came to me still raising sputum containing some blood. Bacilli were found but were not abundant. There were râles in the apex and subjacent area of the left lung. There was the characteristic fever curve. After four weeks of treatment the lung cleared up and the man has continued in apparently the most robust health.

CASE XLI.—Miss C., of Allen, Mich., came under treatment in March, 1895. There is no need of detail in this case. The disease was in an advanced stage with cavities and an afternoon temperature often as high as 103° F. There was temporary improvement indicated by a fall in the temperature and a gain in weight. This was followed by retrogression and a gradual decline.

After her return home Miss C. was under the charge of Dr. Williams of Jonesville, Mich., who has kindly furnished the following:

"After her return home from Ann Arbor, some time in the early summer of 1895, I continued the nuclein treatment, at first by internal administration, with negative results, as demonstrated by rise of temperature from 99⅘° to 103° F. Pulse 130. Respiration 22 to 24. Increase of cough, profuse expectoration, and return of night sweats. I then sent for a large syringe and treated her hypodermically, with the result that temperature, pulse, and respirations, were reduced. Appetite in a measure returned. Cough and expectoration modified, and a seeming arrest of the progress of the disease. This condition continued for about four months, or until late fall. During this time I gave her daily treatments at first, then as better symptoms returned, she came for treatment every other day. I injected from 30 to 80 drops of a one per cent. solution, and without the slightest symptom of an abscess at any time.

"From the first of November, until her death—some three months—the history of her case is that of tuberculosis in the last stage of the dread disease.

"While 'nuclein' hypodermically did not entirely arrest the progress of the disease I am satisfied it prolonged her life several months."

CASE XLII.—Miss O., aged twenty-six, a student, came under observation in March, 1895. Her mother and a sister and a brother of her mother and a brother of her father died of consumption. The mother died five years ago, after a long illness, during which the daughter attended her. This patient has always been frail and anemic. Four years ago her physician told her that one lung was diseased, and three years ago she had a long-continued low fever, which was called typhomalarial. She has coughed for four years. The quantity of sputum raised was small, but I never saw another specimen so rich in bacilli as was this. There was a large cavity on the right side, and râles were heard over the whole of the upper lobe on this side, and from the apex to the base in the left lung. The weight at the time of beginning the treatment was 98 pounds. The patient remained under my treatment until October 7, 1895, having an injection of nuclein nearly every day during this time. In October I could not see that her condition was materially different from what it was in the preceding March. Her weight was 100 pounds, and the physical signs remained practically unchanged. I advised her to go to Colorado, and she did so in October, 1895, and placed herself under the care of Dr. Henry Sewall, of Denver. In February, 1896, Dr. Sewall sent me the following condensed record: "Miss O., aged twenty-seven, with poor development and very anemic. Some percussion dulness and fine râles throughout upper half of right lung, and similar sounds found through the left lung nearly to its base; rather dry, cavernous sounds under right clavicle; pallor of pharynx and larynx, and slight swelling of mucous membrane over and between arytenoids. She has received nuclein injections every second day, or oftener, for two-and-one-half months, and has gained four pounds. Her lungs are drier and the morbid signs are less extensive."

In September, 1896, Dr. Sewall reported the continued improvement of this patient.

Case XLIII.—Miss G., aged twenty-five, of Brighton, Mich., came under my care in March, 1895. Her father died of consumption in 1891, and this young woman, always frail, was a constant attendant in his last illness. The mother is living and well. The patient has one sister, who has been married and away from her father's home for several years. This sister is in good health. A brother, who also was with the father during his sickness, has recently been declining in weight and failing in health. As stated above, the patient had always been frail. Her maximum weight was 108 pounds, and she has always been anemic. In 1893, while at the fair in Chicago, she caught cold, and has been coughing and expectorating ever since. The greater part of the winter of 1894 and 1895 had been spent in the South, but the disease had apparently made rapid progress during this time. At the time of her coming to me she was having "chilly sensations, followed by flushed cheeks, every day." There were small cavities in the right upper lobe, and bronchial breathing over the upper half of the left lung. She continued with me until October, 1895; and her history differs materially and favorably from the others of the same class. Up to the middle of August there seemed to be no improvement, and the afternoon temperature frequently went up to 103° F. At the time mentioned, the maximum daily temperature began to fall, the appetite improved and the weight increased. The physical signs showed marked improvement. During the latter half of September the temperature seldom exceeded 99° F. I thought this a good time to send the patient to Colorado. She went in October, aud has slowly improved without further medication.

Case XLIV.—Mrs. E., aged thirty-one, of Ann Arbor, came to me in April, 1895. One sister had consumption for some years, but died in labor. This sister lived with Mrs. E., and as no precautionary measures were taken, the chance of transmission of the contagion was great. A brother, also, developed the disease, and his case will be mentioned later. For nearly a year Mrs. E. had been losing flesh and complaining of great lassitude. A pulmonary hemorrhage sent her to me. For five or six days she coughed up blood, and this was repeatedly examined. Tubercle bacilli were present, but were not numerous. The source of the hemorrhage was evidently in the left apex. Over the whole of the upper left lobe there was dulness, and moist râles could be heard. The afternoon maximum temperature was for some days as high as 102° F. Treatment was begun immediately, and continued daily until October, 1895. From this time to March, 1896, the injections were made twice a week. Since March the patient has had no treatment. She weighs now 25 pounds more than her maximum weight before April, 1895. I can now (October, 1896) find no trouble in the lungs.

Case XLV.—Mrs. S., aged twenty-six, of Chester, Mich., came under my observation in April, 1895. There was a history of direct contagion. She had helped to care for a consumptive neighbor and no precautions against infection had been taken. The patient was in an advanced stage of the disease. There were numerous small cavities on the left side and consolidation on the right in the upper lobes. The maximum temperature was from 102° to 103° F. The treatment was administered for three weeks without any appreciable effect on the rapid progress of the disease. Death occurred within a few weeks after the patient's return home. In this case there was not even a temporary improvement.

Case XLVI.—V. F., aged twenty-four, a medical student, had a hemorrhage in April, 1895. Tubercle bacilli were abundantly present in the blood. There was the pneumonic infiltration and the characteristic fever of tuberculosis. Treatment was given daily to October, 1895, then omitted to February 25, 1896, then three time per week until June, 1896. The summer of 1896 was spent in the Adirondacks without treatment. During this time the disease progressed. When he left Ann Arbor in June, 1896, he had no cough. On his return he was raising some sputum every morning and this contained bacilli. October, 1896, he has returned to college and I find bronchial breathing over the right apex. He now weighs 145 pounds, more than he ever weighed before, but, as stated above the sputum contains bacilli.

Case XLVII.—G., aged twenty-one, of Ann Arbor, is the first of a class which has furnished me with only a few representatives. There was no hemorrhage, but the patient was brought to me on account of a "bad cold" and a cough which had persisted for "some days." The maximum daily temperature was between 101° and 102° F. going occasionally, but exceptionally, to 103° F. There was bronchial breathing with moist râles over the upper half of the left lung. The sputum contained numerous tubercle bacilli. Treatment was continued until October, 1895. The bacilli disappeared in August, and the cough ceased a little later. The temperature became constantly normal about the time the bacilli disappeared. The râles and the dulness disappeared, and the only suspicious sound heard on auscultation was due to some prolongation of the expiratory act. Late in the fall of 1895 this patient went to Colorado as a pracautionary measure. He remains there and reports himself well. I believe that in this case the tubercular invasion had not extended very far when the treatment was begun.

CASE XLVIII.—Mrs. D., aged thirty, of Ann Arbor, belongs to the same class as the preceding one. She had a cough in February, 1895, when I examined her lungs, and believed from the evidence thus obtained that she had tuberculosis, but repeated examinations of the sputum which she was then raising quite freely failed to reveal any tubercle bacilli and the nuclein was not used. After continuing for two weeks the cough ceased. In April another bad cold with cough and expectoration brought her to me again. This time the bacilli were found. Treatment was given for three months and then wholly discontinued. The cough ceased in a few weeks as it had done before, and she passed through the winter of 1895 and 1896 without a "bad cold." She was pregnant at the time of treatment and has borne a healthy child since. Now, there is no evidence of the existence of tuberculosis.

CASE XLIX.—K., a medical student, aged twenty-five, spent the summer of 1894 partly in taking care of several tuberculous patients. In May, 1895, he had a hemorrhage. In the bloody sputum the tubercle bacillus was easily found. The nuclein treatment was begun immediately and continued for two months. He then went to Colorado and located at Fort Collins where he practices medicine. He reports himself as being quite well.

CASE L.—Mrs. L., of Jackson, Mich., aged thirty-two, came to me in June, 1895. She had three children, all of whom were well. The father was then living and well. Her mother died at the age of forty-one of consumption. Four of her mother's and one of her own sisters died of consumption. She had been with this sister during her illness. The patient began to recognize the fact that she was not well early in the fall of 1894. She began to cough and raise about January 1, 1895. At the time of the first examination she was coughing and raising very profusely. She had exhausting night sweats. The average afternoon temperature for four days before the first injection of nuclein was 102° F. There was bronchial breathing over both upper lobes. The appetite was poor. This patient improved temporarily, then lost what she had gained. The treatment was continued about three months, and the condition at the close of this period showed no improvement. She died in August, 1896.

CASE LI.—Mrs. W., aged thirty-eight, of Lima, O., was first seen early in June, 1895. She had been married fifteen years, and had two healthy children. Her father had died at the age of seventy-six and her mother was then living at the age of eighty. She had seven sisters, one of whom had died about two years before of consumption. She had been with this sister during her illness. She had her first hemorrhage in May, 1894, and had coughed and raised some ever since. Strange to say that during this year she had gained in flesh. She was in good flesh (I find that I failed to record her weight), and did not by any means present the appearance ordinarily supposed to be characteristic of consumption. There was bronchial breathing over the whole of the left upper lobe and over the greater part of the right upper lobe. The amount of sputum raised was small, but it contained the bacilli in great numbers. Her appetite was good, and she retained her healthy appearance as long as she was with me, which was until the middle of October, 1895. This patient did not do well. Hemorrhage followed hemorrhage. The quantity of blood raised at a time was small, but it was continuous. I cannot say that there was even temporary improvement. The temperature seldom went as high as 100° F. In October, 1895, she went to Denver, where she continues to reside. The hemorrhages still occur.

CASE LII.—Miss R., aged twenty-eight, was sent to me by Dr. Steiner of Lima, O., in June, 1895. Father and mother were living and well. One brother died of consumption six years ago. The patient was with this brother during his illness. She had been teaching for eleven years in the public schools of Lima. She had influenza four years ago, and has been more or less hoarse, with some cough, since that time, but she has attributed this condition to the unwholesome air of the schoolroom and to the constant use of her voice. During the vacation of 1894 she worked in the slums of Chicago, although at that time she was feeling much out of health. She first consulted a physician in May, 1895, when she went to Dr. Steiner, who immediately recognized the true nature of her trouble. Respiration over both upper lobes was wholly bronchial. The sputum was purulent and contained numerous bacilli. The maximum temperature averaged 100° F. She rapidly improved temporarily until the middle of August, when she had a chill every other day for a week, her tongue was heavily coated, and she loathed food. A mercurial, followed by large doses of quinin, seemed to remove this trouble, which I regarded as an intercurrent attack of malaria. She soon began to improve, and I consented to her returning to Lima and resuming her work as a teacher. Some three weeks later she suddenly developed a pleuritic effusion on the left side. Some of the fluid was drawn by Dr. Goebel and sent to me. It contained tubercle bacilli. Notwithstanding the most intelligent treatment by Dr. Goebel, the patient rapidly failed, and died in February, 1896.

(To be continued.)

CLINICAL MEMORANDA.

THE VALUE OF "COGWHEEL" INSPIRATION AS AN EARLY SIGN OF PULMONARY TUBERCULOSIS. TWO ILLUSTRATIVE CASES.

By J. P. ARNOLD, M.D.,
OF PHILADELPHIA;
PHYSICIAN TO THE PRESBYTERIAN HOSPITAL DISPENSARY.

IN the physical examination of a number of chests, I have been much impressed with the value of "cogwheel" or interrupted inspiration as a sign of beginning tuberculosis of the lungs. I have found this sign present in cases when there were no changes in the percussion note, or in the vocal resonance, and when there was neither cough or expectoration, yet the patients have subsequently developed very definite physical signs, and showed the presence of tubercle bacilli in the sputum. The importance of an early diagnosis in pulmonary tuberculosis cannot be overestimated, as it is only in the early stages that we can hope to cure the disease. The earlier the diagnosis is made, the better the chance for effective treatment.

It is true that this peculiar form of inspiration may be caused by other conditions than that of beginning tuberculosis; nevertheless, its occurrence immediately below the clavicle, especially on the *left* side, should always arouse our suspicion; and whenever there is an hereditary tendency present, the history of exposure to infection, or any progressive failure of health and strength without other assignable cause, it may be considered a very distinctive sign, and treatment should be instituted at once.

The subjoined cases, occurring within the past year, have brought this more forcibly than ever to my notice. In the first case, the cogwheel inspiration was present with other conditions, which made the diagnosis more certain. Both of the cases occurred in apparently healthy young women applying for admission to the training school of one of our hospitals.

Case I.—R. E., aged twenty-five, weight 116 pounds, height five feet eight inches. A brother had died of phthisis. She had always been quite healthy. The chest was long and flat. The vocal fremitus over the left apex immediately below the clavicle approached that of the right side in intensity (a suspicious sign in itself). Just below the middle of the left clavicle there was very marked interrupted jerky inspiration. Expiration was apparently normal. The percussion note over the apices, while not of the best quality, was not sufficiently impaired to indicate distinct disease. There were no other physical signs present. In spite of advice, this young woman neglected to take proper care of herself, and in the course of three months there were undoubted physical signs of consolidation at the left apex. There was cough, expectoration of nummular sputum, night-sweats, and loss of flesh. There had also been a small pulmonary hemorrhage. Because of the perversity of the patient, I was unable to obtain a specimen of the sputum for microscopic examination.

Case II.—E. M., aged twenty-two, weight 133 pounds, height five feet seven and a half inches. Both parents, two brothers and two sisters living and healthy. No history of lung trouble in the family on either side. The patient was a well-built, healthy-looking girl. The physical examination made at the time of admission was entirely negative, except that a few piping râles were heard over the left apex. The statement that she had recently taken cold, and that she had once had a slight attack of asthma, with the further statement that she had only had a cough for two or three days, with no expectoration, was considered sufficient to explain this sign. Probably the limitation of the râles to the upper lobe should have excited my suspicion, but the character of the râles, the fact that they shifted in position, and the entire absence of other signs, led me to consider the condition trivial.

In the course of about six weeks the young woman was sent to me again, complaining of a cough, substernal pain, and expectoration. There was no loss of weight, and the general health was very good. Temperature taken for several days was always normal. The cough was worse in the morning. The examination of the chest was negative, with the exception of well marked "cogwheel" inspiration below the left clavicle. Several examinations of the sputum showed numerous characteristic tubercle bacilli. I had her under observation for about four weeks after this examination. The physical signs remained the same, and the presence of the bacilli continued in the sputum.

The two cases cited above, I think, illustrate clearly the value of the sign mentioned. The occurrence of the piping râles in Case II., even before the interrupted inspiration, is, I think, unusual. Should it be present in another patient, I would watch the case carefully for the occurrence of other physical signs.

A CASE OF ATYPICAL TYPHOID FEVER COMPLICATED BY THROMBI OF THE RIGHT AND LEFT CRURAL VEINS.

By LAWRENCE ASHTON, M.D.,
OF DALLAS, TEXAS.

Miss B., a resident of Norwich, Connecticut, aged twenty-seven, after two years spent abroad, reached Dallas, September 27, 1895, with slight fever, believed to be due to fatigue incident to travel and change of climate. Not improving, however, I was called to see her eight days after her arrival, when, upon examination, the following conditions were found to exist: Great nervousness, persistent headache, nausea, constipation; tongue coated, with red edges; temperature 103° F., morning; 101° F., evening; pulse 120. This condition of things continued until October 30th, when the exacerbations occurred each evening, ranging from 104° F., in the evening to 101° F., in the morning. November 5th she had a profuse hemorrhage from the bowels, with extreme prostration. The hemorrhages occurred at intervals until November 15th. There were no hemorrhages after this time, but the stools were liquid, very offensive, and passed involuntarily. Fever continued until December 12th. There was constant delirium, which continued for weeks after the patient was free from fever. For several weeks it was necessary to use the catheter, on account of inability to pass urine.

On December 1st the patient complained of pains in the right leg, which soon became greatly swollen, tense, and hot. The pain was so great that nothing afforded relief but large doses of morphin and atropin, administered hypodermatically. As the inflammation in the right limb was subdued, the left leg showed the same conditions, with the most intense suffering imaginable. Later there was marked neuritis of the hands and arms.

Treatment.—The diet, from the beginning, was chiefly of milk, or milk diluted with limewater, aerated waters, or malted milk and beef juice. For the pyrexia the Brand method was strictly carried out, the patient remaining in the bath from fifteen to twenty minutes, being then taken out and wrapped in dry sheets and covered with a light blanket. The antiseptic medication consisted in the administration of small doses of corrosive sublimate, naphthol, carbonate of creosote, and guaiacol. Tympanites and abdominal pain were controlled by turpentine stupes. Hemorrhages from the bowels were treated with opium and acetate of lead, or hypodermics of morphin and strychnin, and by means of an ice-bag applied over the abdomen, which measures, for the time being, always controlled the hemorrhages. The enlargement and edema of the lower limbs, due to thrombi in the crural veins, was treated by elevation of the limbs and local applications of flannels wrung out in extract of witch hazel as warm as the patient could bear it. Strychnin, hypodermically, was administered constantly in gradually increasing doses, until she was taking one-fifteenth of a grain every four hours. She received but little medicine by the mouth, as the stomach rejected almost everything. Alcohol, in any form, was never retained.

The patient made a slow recovery, and not until April 15th, nearly seven months from the time she was taken sick, was she able to return to her home.

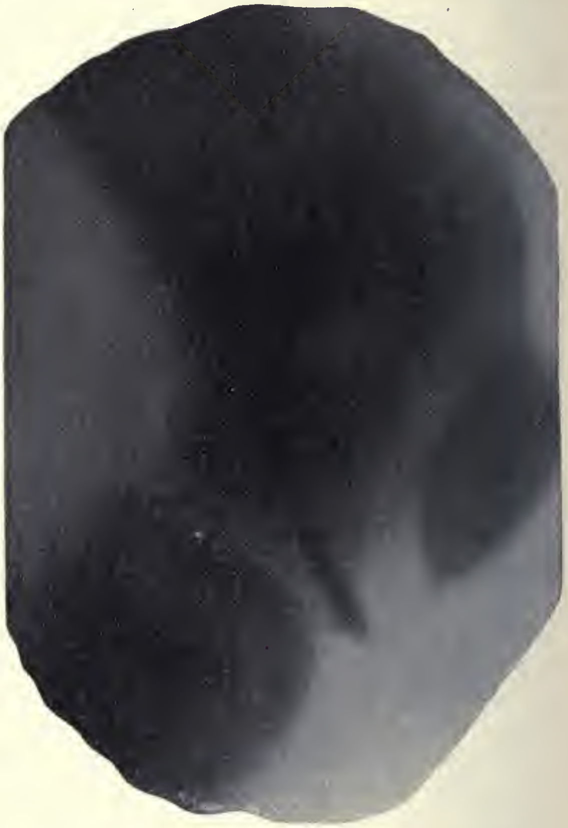
FOREIGN BODY IN THE KNEE-JOINT LOCATED BY MEANS OF THE ROENTGEN-RAY.

By HERBERT B. PERRY, M.D.,
OF AMHERST, MASS.

THE accompanying X-ray photograph is that of the knee of a girl nine years of age. It was taken to demonstrate the presence of, and to locate if possible, the five-eighths-inch missing point of a pair of scissors with which she had wounded her knee four days previously. The history of the case is as follows: Two days before I saw her, while kneeling on the floor, she felt a sharp pain in the left knee. Investigation by her mother revealed a wound about four lines in length, a little below and external to the median line of the patella. What appeared to be the bottom of the wound was cleansed thoroughly, and the child was put to bed.

The scissors found upon the floor where the accident occurred was an old pair, and no member of the family was sure that the broken blade was not in its then condition prior to the accident. When I was called in to see the patient I found that the knee was swollen, hot, tender, and painful. I advised the use of the X-ray, and the procedure was carried out at the Physical Laboratory of Amherst College by Professor Kimball. An electrical current sufficient to produce a 2½-inch spark was used. Before the plate was exposed, I was able to locate the foreign body in the joint by the use of the fluorescent screen. In order to have some landmarks to work by in operating for its removal, a long, flat key, the only available piece of metal of proper shape and size, smeared on the point with ink, was passed between the light and the knee, and the knee and screen, until it was seen to touch the skin at the location of the foreign body. In this way both the distal and proximal end of the scissors-point was noted on the external and internal surfaces of the knee. The mark was afterward made indelible with nitrate of silver.

The next day the child was etherized, the site of the operation having been rendered aseptic, and an Esmarch bandage was applied. An incision was made from the lower border of the patella downward about three inches. The path of the scissors-point could be seen, the blood having settled along its course, and showing clearly in the surrounding bloodless area. It was necessary to open the joint and to divide part of the external lateral ligaments and the quadriceps extensor tendon. Extreme flexion of the leg on the thigh was necessary to enable me to reach the foreign body, and it was found to be embedded for nearly its entire length in the extreme posterior part of the articular surface of the external condyle. The skiagram apparently does not indicate that such was the case. The fact that it was entirely buried may be accounted for by the accidental extension of the leg while the child was being etherized.



Skiagraph of a scissors-point in the knee-joint of a child.

After ten days the dressings were changed for the first time. The wound had healed nicely. During this time the patient had not suffered pain, and the temperature did not rise above normal. Six weeks have elapsed since the operation. The knee is movable, and I look for practically complete recovery of function.

MEDICAL PROGRESS.

Supposed Precocious Menstruation.—The reports of menstruation in infancy and childhood which are so often made are not to be too readily accepted. COMBY (*L'Union Médicale*) found ordinary vulvo-vaginitis sometimes accompanied by distinct hemorrhages. In three cases of children, of two, three, and six years of age, which had been mentioned as instances of precocious menstruation, he found that the blood came not from the uterus, nor from the vagina, but from vascular granulations about the meatus urinarius, which bled freely if touched. This condition was cured by weak injections of permanganate of potassium and cauterization with a 1 in 50 solution of nitrate of silver.

A Point in the Diagnosis of Renal Calculus.—BROOK (*Brit. Med. Jour.*, December 19, 1896) narrates two cases of renal calculus in which the diagnosis was obscure. In both cases heavy percussion below the tip of the last rib caused acute stabbing pain in the loin. The writer looks upon this symptom as a most valuable, though little known, means of diagnosis of renal calculus. In his two cases the urine was repeatedly examined microscopically, but neither blood or pus was ever found. The absence of this peculiar pain does not, of course, negative the existence of a stone. The character of pain caused by percussion in a case of impacted gall stone or abdominal inflammation, such as appendicitis, is not the same as when a renal calculus exists.

Relation of Adenoids to Deafness.—FRANKENBERGER (*Centralbl. f. Chir.*, No. 50, 1896,), who examined 159 children in the deaf mute institute in Prague, found hypertrophy of the tonsils in 94—that is, $59\frac{5}{10}$ per cent. In 42 cases there was evidence of alterations in the middle ear, either chronic suppuration or its sequela. Of these 42 children, 37—that is, 88 per cent.—had adenoid growths. The frequency of the occurrence of adenoids in deaf mutes has often been noticed, and the writer believes, with other recent authors, that deafness is many times due to acquired disease in cases which are classed as congenital, and that prophylactic and therapeutic measures would have saved hearing and speech in such cases.

The Application of Schleich's Method of Cocainization.—GOTTSTEIN (*Centralbl. f. Chir.*, No. 50, 1896) published results of cocainization by the method of infiltration in 118 operations. Nearly one-half of these were for the extirpation of tumors. There were eight cases of resection of the vas deferens, two cases of strangulated hernia, ten gastrostomies, and several exploratory laparotomies. One advantage of this method is that the patient can usually get down from the table immediately after the operation, so that hypostatic pneumonia, which so often follows ether operations in feeble patients, is avoided. It was a great pleasure to observe how slight a reaction followed these "major" operations. As far as possible an Esmarch bandage was used after the injections were made. The anesthesia usually lasted thirty minutes, sometimes still longer. In only two cases was there any evidence of cocain intoxication.

A Giant Fetus.—OLANO (*El Monitor Medico*) performed an autopsy upon a well-formed woman, aged thirty-nine, who had died after four days of labor pains and an unsuccessful attempt to deliver the child by forceps. The fundus of the uterus was just under the liver. It contained a well-formed female fetus with the head downward, which measured 68 centimeters (27 inches), and weighed 10,000 grammes (26 lbs.). The mother had had three normal and two premature confinements. There was non-medical and purely subjective evidence to the effect that the woman was many months past full term.

Respiratory Gymnastics in the Treatment of Disease.—CAMPBELL (*British Medical Journal*) finds that respiratory exercises favor the circulation of blood and lymph and promote the normal action of the abdominal organs. They are of service, therefore, not only to patients with cardiac affections, but to many of those who suffer from functional nervous diseases. Respiration is of three types—diaphragmatic, that in which the lower ribs are involved, and a purely costal respiration. That type is chosen, which is especially fitted to the disease to be treated.

Abscess of the Brain—Localization, Treatment.—STIERLIN (*Korrespondenzbl. f. Schweiz. Aertze*, No. 15, 1896) reports a case in which a railroad laborer, twenty-six years of age, about eight days previous to his entrance into the hospital, was struck on the forehead with a large stone with such force as to render him unconscious for half an hour. A bandage was applied and, in the meantime, he went about feeling tolerably well. On admission to the hospital a large gaping pus-discharging wound was found in the soft parts covering the left forehead. The base of the wound was formed by the frontal bone denuded of periosteum, in which there was a gaping, depressed fracture. In the bone fissure radiating from the central depression a piece of felt from the patient's hat was included. Resection was performed. The dura was intact. A tampon of iodoform gauze was used. In the beginning no marked reaction was discernible. About the tenth day, however, the patient was overcome by a heavy drowsiness and psychical changes were observed. About fourteen days after the operation involuntary urination and defecation supervened. Increasing debility, apathy, and a continuously increasing diminution in the force of all the vital functions, together with a noticeable paralysis of the right side of the face, set in. There was no fever. The diagnosis of abscess of the brain was made. Eighteen days after the onset of the first symptoms, the presence of pus in the brain having been first positively ascertained by an exploratory puncture, a large abscess in the left frontal lobe was opened. More than 100 cubic centimeters of ropy pus was evacuated, the cavity being twelve centimeters in width. The cavity at first was drained with strips of iodoform gauze; later, with rubber tubing. A small pulsating, prolapsing portion of the brain substance was held in place by compresses. The wound in the brain substance required more than two months for cicatrization. Three and a half months after the incision, and about forty-five days after complete cicatrization of the wound, the defect in the bone was covered up by grafting. Recovery was complete. As regards the exploratory puncture in cases of brain-abscess, Stierlin advocates the method of von Bergmann, namely, to use the knife instead of the needle, in substantiation of which he cites a case in which, after trephining, the exploratory puncture was negative, notwithstanding that the autopsy showed a large abscess in the parietal lobe just beneath the part trephined.

Bronchial Asthma Occurring Only During Menstruation.—The so-called asthma uterinum is of rare occurrence, and its existence has been disputed by some. Katz reports a case in which the sputum possessed characteristic features of asthma, namely, Leyden's crystals, spirals, and sago-like pellets. The attacks of asthma and this characteristic sputum were present only during the menstrual period. The patient, aged thirty-two years, was in every other respect healthy. Nothing in her family or personal history explained the occurrence of these asthmatic attacks, which had existed about a year.—*Deutsche Med. Wochenschrift*, Dec. 10, 1896.

An "Epidemic" of Appendicitis.—GOLOUBOFF (*Gazette Médicale*, December 26, 1896) considers the possible epidemic nature of appendicitis. He refers to the usual rarity of the affection in Moscow, and to the sudden appearance there of a number of cases. Three pupils in one school who occupied the same bench were attacked by the disease on the same day. Appendicitis is thought to be caused by the microörganisms of the intestine. Under the action of causes as yet unknown, the coli bacillus, the streptococcus, and staphylococcus suddenly take on a more than ordinary virulence. Golouboff compares the epidemics of appendicitis to the little epidemics of tonsillitis which frequently occur.

Artificial Respiration in Intrathoracic Operations.—TUFFIER and HALLEON (*Gazette Hebdom. de Med. et de Chir.*, No. 95, p. 1131) report experiments upon dogs under chloroform, in which, by means of a tracheal tube and bellows, the movement of the lung may be so contracted as to avoid pneumothorax after opening the pleural cavity, and to simulate normal respiration during such operations. By this method, aided by an incandescent lamp, much of the pleural cavity and the mediastinum is accessible to operation. The insufflated air should he sterilized by heat. No complications or disturbance of pulmonary circulation have followed this procedure.

THERAPEUTIC NOTES.

Cresal in Typhoid Fever.—POSAGUY (*Medicius Koié Obosrenié*) has employed cresal in eighty-seven cases, as an emulsion in water and given in milk. Beginning with fairly large doses, these were increased up to forty-five or even to ninety drops per day.

There were no complications and no changes in the urine. The tongue and mouth became clearer, meteorism diminished, the patients felt well, and appetite returned. The stools decreased to one or two per day, lost their offensive odor, and took on their normal form. The febrile period was diminished to six days. Finally, a mortality of 2.41 per cent. resulted.

What Cases of Obesity are Suitable for Thyroid Treatment?—According to a writer in the *Gazette Hebdomadaire*, January 24, it is desirable to distinguish two classes of fat people. Those who are young, vigorous, and plethoric, and who are good livers, receive little or no benefit from thyroid treatment. Such cases are benefited by a dietetic regimen. On the other hand, fat persons that are pale, soft, and flabby, and inclined to edema, receive benefit from the ingestion of the thyroid gland. They lose weight rapidly, oxidation is increased, and nutrition improved. This "torpid" obesity, which has some points of analogy with this edema, is seen most frequently in women, while "florid" obesity occurs usually in men.

Enteroclysis in Gastro-Intestinal Disorders.—THIERCELIN (*Revue de Ther. Med. Chir.*, No. 23, p. 709), after a historical résumé, considers that flushing of the intestinal tract is advisable, and should be tried in every case, acute or chronic, of gastro-intestinal trouble, especially in children, as in this way the intestinal canal is freed of irritating, fermenting material, fermentative germs, and their toxic products, much better than by purgatives. When fever is present, one or two liters, at 25° C., can be injected very slowly several times a day. In the algid types, however, water, at 38° to 39° C., is used. The absorption of some of the water acts favorably upon the thirst, the hepatic and renal circulation, and the cardiac action. Boiled water, weak saline solution (seven grammes of sodium chlorid to the liter), weak boric-acid solution, alkalin, and lactic-acid solution, may be used, according to the case. The injections should not be continued longer than four or five days. They are contraindicated in cases of cardiac affection, in stricture of the intestine, and in ulceration, though some favorable reports of the use of a creolin solution in typhoid are on record.

Contraindications to Salicylates in Acute Articular Rheumatism.—According to JACCOUD (*Semaine Médicale*, No. 54, p. 34), salicylate of soda is contraindicated in acute articular rheumatism with marked visceral complications. In such cases he uses the tartrate of antimony in large doses. Opium is incompatible, as it prevents the elimination of the drug by diminishing the emesis and diarrhea. Fever is permanently reduced by the third day, and no case of pericarditis has been observed. The author quotes from statistics the proportion of cardiac complications under salicylates as being from four to eight per cent.

Salicylate of Soda for Hemoptysis.—MAYS recommends, in the *Journal de Médicine*, Paris, January 24, for the treatment of the profuse and persistent hemoptyses which sometimes occur in patients with rheumatic or gouty diathesis, salicylate of soda, which he has used with remarkable effect in such cases.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, MARCH 20, 1897.

PATHOLOGY GONE MAD.

WE have had occasion to note from time to time that the persons devoting themselves to one particular line of work become so engrossed with their individual studies that their minds receive an indelible impression, which tinctures all they write and say; and particularly if they are studying pathology their point of view actually becomes pathological. We believe that no one will deny the assertion that the whole object of bacteriological, pathological, and other medical studies is the improvement of our knowledge in regard to the process of disease, in order that we may gain information as to the proper methods for the relief, or cure, of the malady before us. Certain it is that the patient, and the average physician, considers the treatment of his case far more important than the study of the pathological lesions underlying it. The one brings direct results, the other only indirectly helps the individual who is in difficulty.

Our attention has been called to this matter, first, by an exceedingly able and practical article by Sir Dyce Duckworth, in the Liverpool *Medico-Chirurgical Journal* for January, 1897, in which he points out the fact that, while pathological and bacteriological studies are of immense value, they are worth nothing to practical medicine unless they point the way toward relief; and the antithesis of this is found in an extraordinary editorial in *The Journal of the American Medical Association* for March 6, 1897, entitled, "The Materia Medica Collection of the Smithsonian Institution." Evidently the writer is a pathologist, who has so lost sight of the ultimate reasons for his existence as to express views which are in direct opposition to every effort of the majority of the profession, and he is also guilty of the following sentence, which we have endeavored to parse, with poor results: "In this time of improved medical education, when laboratory, clinical, and dead-house teachings, with improved hygienes, tend daily to make the administration of drugs the approbrium of medicine, and much of the study of our own profession a mere meditation upon death." He then proceeds to quote Dr. Loomis of New York as having said: "Young men prescribe the drugs, but we old fellows don't believe in them."

The position of the physician who is optimistic in regard to the value of remedies in the treatment of disease is certainly that of the man who is striving after that which is desirable and good, but the position of one who is a therapeutic nihilist is equivalent to that of a man who, standing on the housetop, announces to the world that "There is no God." Theapeutics, or the treatment of disease, lacks certainly not because it is at fault itself, but because pathologists are unable to explain the process of disease. When the underlying factors producing disease are laid bare to us by the pathologist it is usually found that the therapeutist can devise a means for its relief or cure, and in many instances practical physicians have managed to relieve maladies, the causes and characteristics of which the pathologists have been unable to explain or discover.

THE MEDICAL TREATMENT COMPANY OF NEW YORK.

IF a rest from his labors is what the doctor longs for, verily his millenium is at hand. Hospitals, clinics, and dispensaries have long since considerately lightened his labors, but it remained for a private company to put him completely at his ease by providing for patients too lazy or proud to go to dispensaries. The general practitioner has for some time been in doubt as to whether the public really needed him, but now all doubt has been cast aside, and he can get a job in the woodyard of the Charity Organization Society or retire to the almshouse, from whose tranquil precincts he can watch the death-throes of legitimate medicine.

During the past month doctors about town have been asked to serve as district physicians for the above-mentioned company. Extracts from its prospectus are as follows:

> "THE MEDICAL TREATMENT COMPANY.
> INCORPORATED UNDER THE LAWS OF
> THE STATE OF NEW YORK.
> OFFICE: 19 PARK PLACE, NEW YORK CITY.
>
> "For $1 a month the Medical Treatment Company provides a doctor as often as you need one, who will treat you or your family at his office, or at your home, as the severity of the case requires, and has the prescriptions filled at the druggist's without extra cost to you. . . . The medical staff is composed of physicians who are graduates of the leading medical colleges of this state, and are in every way fully qualified by experience to treat any case of disease. . . . The birth of a child is a physiological condition, and therefore not classed under medical treatment. Under our system, upon payment of $5, at the time of the birth, to the attending physician, the mother will receive proper attention during convalescence."

To the unthinking the workings of this company may appear somewhat revolutionary, but to one who has watched the signs of the times it seems only the legitimate outgrowth of the commercial spirit which has invaded and is likely to engulf medicine. That such a company may receive patronage enough to insure financial success is possible, and that it can hire regular physicians to do its work is probable. The extent to which the public will go for "bargains" has no limit and the willingness with which doctors will do contract work is well known. This scheme simply organizes the city of New York into a vast lodge for the purpose of getting medical service and medicines at rock-bottom rates. That the services and medicines obtained will probably be on a par with the price paid for them will undoubtedly be true, but that generally holds good for all "bargains" and does not render them less popular.

However unethical the whole procedure seems to us of the old school of ethics and practice, we see nothing illegal in it, and the profession stands in much the same position toward it as the small shopkeeper does to the big department store. The great possibilities of the movement are all that should startle us, as the same reprehensible practice has been carried on for twenty years by the Society of the New York Hospital in its out-patient department. In fact "The Medical Treatment Company" is more worthy of respect as it pays its physicians a salary.

Surely the (downward) path of the doctor is being made easy and he may soon say with Solomon, Eccl. iii, 9, "What profit hath he that worketh in that wherein he laboreth?"

MUNICIPAL FREE BATHS IN NEW YORK.

PLAGUE and pestilence follow on the heels of famine for the reason that famine and destitution bring squalor and filth. *Pari passu* with the evolution of the germ theory of disease, the conviction has grown that the fundamental and universally applicable prophylaxis against all disease lies in hygienic habits and sanitary surroundings. Fresh air, and an abundance of it, and a generous supply of pure water are nature's great safeguards against disease. The one destroys disease and gives to the blood corpuscle the power to resist it, while the other washes it away beyond the possibility of doing harm.

It is with no slight degree of satisfaction, therefore, that we read the report which has just appeared of the committee on public baths and lavatories which was appointed two years ago by the mayor of New York. The committee has evidently given a vast amount of investigation and study to the subject; the report is replete with information and valuable suggestion.

The necessity for public baths was at once made apparent when the committee visited the tenements and lodging-houses to learn what bathing facilities were there afforded. Out of 480 houses visited in the slum districts, it was found that only 17 had bathrooms. Particularly inadequate provisions for bathing in the lodging-houses were noted, the patrons of many of which are, by reason of their bodily filth, a menace to the safety of the community. In 112 lodging-houses 15,233 persons are allowed to lodge by the authorities. Of these 112 houses 55 are without baths of any kind, and in these 55 houses 6372 lodgers are allowed. Fifty-seven houses have 95 baths, and the whole number of lodgers allowed in these houses is 8861. Fifty-six of the baths ostensibly have hot water. In 54 houses the baths are free, in 3 they are paid for. The average number of baths taken daily is 546. The replies of some of the patrons of the houses, when asked their opinion of the bathing accommodations, were: "The tubs are never cleaned out, from the appearance of them;" "can't get a good wash without hot water;" "find too many old medicine-bottles for my taste;" "bad enough to sleep in a lodging-house, without using their baths." The committee also quotes from the report of the Gilder tenement-house committee the statement that, out of a population of 255,033 covered by the committee's inspection, only 306 persons had access to bath-rooms in the houses in which they lived.

It is interesting to know how similar conditions are met in the cities of the old world. The committee found that the city of Birmingham, with a population about the same as Boston, possesses four complete sets of well-appointed baths, and one open-air swimming bath. Two of the baths have a Turkish bath attached. In no case are the English or continental baths free, and the operating expenses are nearly met in almost every case by the fees. At Birmingham the fees are from one penny to sixpence, and a complete Turkish bath, including shampooing and the use of a private dressing-room, costs but one shilling. Liverpool is but little behind Birmingham. In "municipal" London over £500,000 is invested in public baths and laundry establishments, which cost £110,000 annually to maintain. Glasgow, not satisfied with providing public baths and laundries, has considered the project of gratuitously teaching everybody to swim.

At the present time the principal facilities afforded to the public of New York for bathing, by both the municipality and private philanthrophy, consist of fifteen floating baths along the water front, which can be used of course only during the summer. How much these are appreciated and how well they are patronized is shown by the fact that from June 20 to October 10, 1896, they supplied accommodation to more than five million bathers.

The committee's idea of a public bath is an establishment under the control of the municipality where a hot or cold bath may be obtained at any time during the year. The plans propose a two-story bath-house containing eighty baths, of which forty-two will be for men, fifteen for boys, and twenty-three for women. Only fourteen of these will be tub baths, the rest being spray baths, mostly of the "ring" variety. The house will be divided into male and female departments. The baths themselves are to be constructed of white-enamelled iron, marble, and unbreakable glass. Each bath will have two compartments—a dressing-room and a room for the bath itself. The floors throughout will be of solid masonry, no iron beams being used, the object being to prevent cracking. The flooring will be of white vitrified tiling. In the basement there will be a free lavatory containing water closets, etc. On the second floor will be a laundry. The German or "Gegenström" system is recommended for heating the water. The waiting-rooms and main bathing-halls will have an abundance of windows and skylights and light-reflecting surfaces. The exterior will be classic in style, and it is recommended that the material used be light in color. The baths, it is said, should readily accommodate 1,000,000 bathers a year, if kept open as required by law and properly administered.

It is recommended that six such bath-houses be constructed in the most desirable localities of the city on lots 100 x 50 feet. The style of bath approved is the spray or shower bath.

It only remains now to secure the appropriation of the necessary funds to put this health-giving, life-saving system into practical operation. The laws of 1896 authorized the Commissioner of Public Works, with the consent and approval of the Board of Estimate and Apportionment, to erect in the public parks so many structures for free public baths and public comforts as the Commissioner and board should deem necessary and proper, and sanctioned an appropriation of $200,000. In accordance with this provision one bath-house, to contain sixty-nine baths, will be built in the new East Side Park, but it is hoped that the law may be so modified as to permit the erection of the other bath-houses in more suitable and convenient places.

ECHOES AND NEWS.

Does Small Lung Capacity Predispose to Consumption?—Dr. Edward Playter, of Ottawa, Can., desires to investigate this question, and asks the profession to send him data giving exact measurements of individual cases.

Diphtheria Regulations in Buffalo.—The Board of Health of Buffalo has issued a circular announcing the fact that it is prepared to make bacteriological examinations of cultures from all suspicious throats, and for the convenience of the profession has placed culture tubes at all the police stations throughout the city.

Anesthetics and the Laity.—Governor Black of New York has signed the bill making it a felony for a person other than a duly licensed physician to have an anesthetic on his person with the intention of administering the same to another person, and makes the finding of the same on the person by any one presumptive evidence of guilt.

Anti-cigarette Bill.—The New York Assembly committee on public health has reported favorably a bill prohibiting the sale of cigarettes to minors, and providing that dealers in cigarettes shall pay a license fee. The bill is amended by making it a violation to sell within 250 feet of a church or school. The bill fixes the license fee at $50.00.

Epilepsy Mistaken for Hydrophobia.—At a recent meeting of the Paris Academy of Medicine, M. Megnin pointed out that current statistics regarding hydrophobia were entirely misleading, as many dogs were declared mad when they simply had epileptic fits. He added that dogs, like human beings, seemed to be more inclined to nervous diseases than formerly.

Ordinance Against Cocain.—It is reported that the victims of the cocain habit have become so numerous in Chicago that an ordinance has been introduced prohibiting the sale of remedies for catarrh and other diseases, which contain cocain. In the last two months over forty victims of the drug have appeared in police courts and elsewhere. Several of them have been well-known men and women, who say they were brought to their present condition by using catarrh cures.

New Quarantine Hospitals at New York.—The Quarantine Commissioners have had plans prepared for the improvement of Swinburne Island, and have asked the Legislature for $300,000 with which to put up a permanent hospital plant. The plans that have been prepared and submitted to the Legislature are based upon the latest improvements in hospital building. They call for the erection of fifteen fireproof buildings made of terra cotta and steel. If the plans are carried out, together with proposed improvements on Hoffman Island, New York will have the finest quarantine station in the world.

The Methods of Quacks.—The *Sanitarian* quotes *The Christian Advocate* as saying: "One of the most amusing, and the same time said things, is to see certificates published in religious papers and others, signed by men certifying that they have been cured of disease by a contrivance or a medicine which is an infallible cure for the maladies spoken of, when to our certain knowledge the signers of the said certificates died subsequently of the same disease. We have noticed fifteen cases of as many different remedies, which in corroboration of this statement we could publish were it not for the grief it would give the bereaved, and were we to publish them without the names, the venders would deny the facts.

The Spitting Ordinance Enforced.—For the first time in New York city a man was arrested, March 9th, and punished for making a beast of himself by spitting all over the floor of a public vehicle. It is not a great many years since it was generally believed that spitting in public was one of the rights of a free people, and not a disgusting habit fraught with danger to the public health. On account of the difficulty experienced in enforcing the order of the Health Department of St. Louis, Mo., against spitting on the floors of cars, it has been suggested that a few cars be run over the lines with the placard "spitting cars" attached. The *Sanitarian* remarks that "this innovation would certainly arrest the attention of the human hog and perhaps work his cure."

Connecticut Vital Statistics.—The annual report of the Connecticut State Board of Health for 1896, just presented, gives the vital statistics of the State for 1895. For the ten years ending with and including 1895 it shows a decrease from 1364 to 1358 in the annual number of deaths from consumption, notwithstanding the increase of about 130,000 in the population of the State during that time. Heart disease during the same time rose from 689 to 1016 a year, pneumonia from 827 to 1289, Bright's disease from 344 to 605, and bronchitis from 197 to 539. Deaths from insanity have increased during that period about 60 per cent. Typhoid fever shows the slight annual increase during these years from 244 to 259. Thirty years ago the deaths from that disease were 332, and as far back as 1855 they were 273. The decrease, in spite of defective returns during the earlier period and the large increase of population since, indicates the effectiveness of the measures to check the spread of the disease. The report strongly approves the use of antitoxin in diphtheria, recommends that a public supply of it be free, and commends bacteriological examinations in the same disease.

Obituary.—Dr. Ernest F. Hofmann, of 45 West Twenty-fifth street, New York, died March 11, 1897, after a four weeks' illness. He was born in Coburg, Germany, in 1832, and came to this country when twenty years old. After studying under various doctors in this city, he graduated from the New York University in 1858. For six years his home was in Poughkeepsie. During the war he served for some months in the Sixth Army Corps, subsequently returning to Poughkeepsie, where he had married Miss Laura Skeel, a painter and skulptor. He came to this city in 1867 to occupy a chair in the Medical College for Women, which he resigned after a year.—Dr. George A. Sterling, for many years a leading physician of Long Island, died in Oakland, Cal., March 8th. He was a native of Sharon, Conn., and a graduate of Bellevue Hospital Medical College. He settled in Sag Harbor, L. I., where he became a successful practitioner. He also had a large practice among the wealthy summer residents of the Hamptons. Failing health interrupted his career, two years ago. Last November he left for San Francisco, intending to go to the Sandwich Islands and establish a coffee plantation, and, if possible, regain his health. When he reached San Francisco he was too ill to proceed. Death was due to stomach disorder. He was about fifty-five years old.

Bones Fractured by Muscular Action.—Dr. C. J. Edgar, in the *Montreal Medical Journal*, reports an interesting and unusual case of fracture of the scapula by muscular action alone. A man aged about forty-five, tall, spare but muscular, was driving a heavily laden team down a somewhat steep incline and walking beside the load, when part of the harness broke, and, to prevent the wagon running upon the horses, he caught hold of one wheel by the spokes with both hands. The impetus, however, was too great, and he was gradually forced over and down upon one knee. As his knee touched the ground, he felt something give way in his left shoulder and lost his hold. On rising to his feet he found the arm powerless and very painful, the pain being referred to the shoulder joint, which he thought to be dislocated. On manipulation of the scapula, it was found that the entire inferior angle was torn away and separated from the rest of the bone by half- or three-quarters of an inch. Firm union was secure in seven weeks, leaving, however, a very marked ridge of callus over the seat of fracture. Motion was perfect, and the arm regained all its former usefulness. A case has been recently reported from San Francisco in which the pitcher of a baseball club fractured his humerus in three places, by the effort he put forth in throwing a line ball from third to first base. And within ten days thereafter another similar case occurred at the same place, the fluoroscope showing a double fracture of the bone.

ANNOUNCEMENTS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE preliminary program for the Fourth Session, to be held in Washington, D.C., May 4, 5, and 6, 1897.

President, William H. Welch, M.D., LL.D., Baltimore, Md.

Vice-presidents, *ex-officio*: President of the American Otological Society, Dr. Arthur Mathewson, Brooklyn, N. Y.; President of the American Neurological Association, Dr. M. Allen Starr, New York City; President of the American Gynecological Society, Dr. James R. Chadwick, Boston, Mass.; President of the American Dermatological Association, Dr. James C. White, Boston, Mass.; President of the American Laryngological Association, Dr. Charles H. Knight, New York City; President of the American Climatological Association, Dr. E. Fletcher Ingals, Chicago, Ill.; President of the Association of American Physicians, Dr. J. M. DaCosta, Philadelphia, Pa.; President of the American Association of Genito-Urinary Surgeons, Dr. Francis S. Watson, Boston, Mass.; President of the American Orthopedic Association, Dr. Samuel Ketch, New York City; President of the American Physiological Society, Dr. Russell H. Chittenden, New Haven, Conn.; President of the Association of American Anatomists, Dr. Frank Baker, Washington, D.C.; President of the American Pediatric Society, Dr. Samuel S. Adams, Washington, D.C.; President of the American Surgical Association. Dr. John Collins Warren, Boston, Mass.; President of the American Ophthalmological Society, Dr. George C. Harlan, Philadelphia, Pa.

Chairman of the Executive Committee, Landon Carter Gray, M.D., New York City.

Secretary, William H. Carmalt, M.D., New Haven, Conn.

Treasurer, Newton M. Shaffer, M.D., New York City.

PROGRAM:

The meetings of the Congress will all be held in the Columbia Theater, corner of Twelfth and F streets, N. W.

TUESDAY—MAY 4TH.

A business meeting of the Congress will be held from 1.30 to 2 P.M.

From 2 to 3.30, a general meeting of the Congress, under the direction of the American Ophthalmological Society.

Subject: "The Gouty and Rheumatic Diatheses, and their Relation to Diseases of the Eye." Papers will be read by Dr. Charles Stedman Bull of New York City; Dr. S. Oliver Richey of Washington, D. C.; Dr. S. D. Risley of Philadelphia, Pa.; Dr. Robert Satler of Cincinnati, Ohio; and Dr. R. A. Reeves of Toronto, Canada; to be followed by a discussion, in which Dr. J. M. DaCosta of Philadelphia, Pa., and Dr. Henry M. Lyman of Chicago, Ill., members of the Association of American Physicians, and others, will participate.

From 3.30 to 5 P.M., a general meeting under the direction of the American Otological Society.

Subject: "Otology in its Relations to General Medicine." A paper by Dr. Clarence J. Blake of Boston, Mass.

WEDNESDAY—MAY 5TH.

From 2 to 5 P.M., general meeting of the Congress, under the joint participation of the Association of American Physicians, the American Physiological Society, and the American Pediatric Society.

Subject: "Internal Secretions Considered in Their Physiological, Pathological, and Clinical Aspects." Dr. William H. Howell of Baltimore, Md., and Dr. Russell H. Chittenden of New Haven, Conn., will speak in behalf of the American Physiological Society; Dr. J. George Adami of Montreal, Canada; Dr. James J. Putnam of Boston, Mass., and Dr. Francis P. Kinnicutt of New York City, in behalf of the Association of American Physicians, and Dr. William Osler of Baltimore, M.D., in behalf of the American Pediatric Society. The papers will be followed by a discussion.

WEDNESDAY, MAY 5TH.—EVENING MEETING.

8.15 P.M., address by the President of the Congress, Dr. William H. Welch, Professor of Pathology in the Johns Hopkins University, Baltimore, Md., to be followed by a reception by the President, at Rauscher's, corner of Connecticut avenue and L. street.

THURSDAY—MAY 6TH.

From 2 to 3.30 P.M., general meeting of the Congress, under the direction of the American Orthopedic Association.

Subject: "Deformities of the Hip-Joint, Especially Congenital Dislocations." A paper will be read hy Dr. E.

H. Bradford of Boston, Mass., to be followed by a discussion by Dr. V. P. Gibney of New York City and Dr. Harry M. Sherman of San Francisco, Cal.

From 3.30 to 5 P.M., general meeting of the Congress under the direction of the American Surgical Association. Subject: "The Classification of Acute General Peritonitis; the Prognosis and Treatment of the Different Varieties." Dr. William S. Halsted of Baltimore, Md., will read a paper on the classification, and Dr. Robert Abbe of New York City, on the prognosis and treatment of the different varieties. A discussion will follow, participated in by Dr. John Homans of Boston, Mass., Dr. A. Van der Veer of Albany, N. Y., Dr. Henry H. Mudd of St. Louis, Mo., Dr. Frederick Lange, and Dr. Arpad G. Gerster of New York City.

AMERICAN PEDIATRIC SOCIETY.

THE Ninth Annual Meeting, to be held at Washington, May 4, 5, and 6, 1897.

PRELIMINARY PROGRAM:

1. "The President's Annual Address." Samuel S. Adams, M.D.
2. "A Case of Tic Convulsif." J. C. Wilson, M.D.
3. "A Brief Analysis of 100 Cases of Frank Pneumonia." F. Gordon Morrill, M.D.
4. "A Case of Acetanilid Poisoning in a Newly-born Infant." Irving M. Snow, M.D.
5. "Antitoxin and Intubation in the Treatment of Diphtheritic Croup." J. Lewis Smith, M.D.
6. "Synopsis of Fifty-eight cases of Empyema Operated Upon During 1896, in the Children's Service of Mount Sinai Hospital." B. Scharlau, M.D.
7. "Adherent Pericardium in Children." Wm. Osler, M.D.
8. "Lithemia in Children." B. K. Rachford, M.D.
9. "A Case of Diphtheria of the Eye." T. M. Rotch, M.D.
10. "An Unusual Case of Erythema Multiforme." Floyd M. Crandall, M.D.
11. "A Case of Edema in Infancy." J. P. Crozer Griffith, M.D.
12. "Multiple Purulent Arthritis with Gonococcal Vaginitis." L. Emmett Holt, M.D.
13. "Retained Intubation Tubes; Causes and Treatment." Joseph O'Dwyer, M.D.
14. "Hereditary Tendency in Pediatric Practice." Floyd M. Crandall, M.D.
15. "Retro-pharyngeal Abscess." J. P. Crozer Griffith, M.D.
16. "Abrasion of the Umbilical Wound." Irving M. Snow, M.D.
17. "Murmurs and Heart Lesions in Infancy." William P. Northrup, M.D.
18. "A Frequent Significance of Epistaxis in Children." J. Henry Fruitnight, M.D.
19. Report of the Committee on the Collective Investigation of Antitoxin Treatment of Pharyngeal Diphtheria in Private Practice.
20. "A Case of Suppurative Nephritis." Rowland G. Freeman, M.D.
21. "Varicella Gangrenosa; a Case." W. F. Lockwood, M.D.

A session is to be devoted to the demonstration of apparatus and pathological specimens. It is requested that announcements of such subjects be forwarded as early as possible. In order to group papers on kindred subjects in the same session, the titles of further papers are also requested at an early date.

Samuel S. Adams, M.D.,
President.

William P. Northrup, M.D.,
Chairman of Council,
57 East Seventy-ninth street, New York.

AMERICAN MEDICAL ASSOCIATION.

THE Forty-eighth[1] Annual Session (fifteenth anniversary) will be held in Philadelphia, Pa., on Tuesday, Wednesday, Thursday, and Friday, June 1, 2, 3, and 4, commencing on Tuesday at 10 A.M.

ADDRESSES.

"The Presidential Address," Nicholas Senn, M.D., Chicago. "Address in Surgery," Wm. W. Keen, M.D., Philadelphia. "Address in Medicine," Austin Flint, M.D., New York. "Address in State Medicine," John B. Hamilton, M.D., Chicago.

COMMITTEE OF ARRANGEMENTS.

H. A. Hare, M.D., 222 South Fifteenth street, Philadelphia.

OFFICERS OF SECTIONS.

Practice of Medicine.—J. H. Musser, M.D., Philadelphia, Chairman; J. T. Priestly, M. D., Des Moines, Iowa, Secretary.

Obstetrics and Diseases of Women.—Milo B. Ward, M.D., Topeka, Kan., Chairman; Geo. H. Noble, M.D., Atlanta, Ga., Secretary.

Surgery and Anatomy.—Reginald H. Sayre, M.D., New York, Chairman; Bayard Holmes, M.D., Chicago, Secretary.

State Medicine.—Elmer Lee, M.D., Chicago, Chairman; Louis Faugères Bishop, M.D., New York, Secretary.

Ophthalmology.—G. E. de Schweinitz, Philadelphia, Chairman; H. M. Starkey, M.D., Chicago, Secretary.

Diseases of Children.—Jas. A. Larrabee, M.D., Louisville, Ky., Chairman; H. E. Tulley, M.D., Louisville, Ky., Secretary.

Dental and Oral Surgery.—R. R. Andrews, M.D., Cambridge, Mass., Chairman; Eugene S. Talbot, M.D., Chicago, Secretary.

Neurology and Medical Jurisprudence.—W. J. Herdman, M.D., Ann Arbor, Mich., Chairman; Chas. H. Hughes, M.D., St. Louis, Mo., Secretary.

Dermatology and Syphilography.—A. Ravogli, M.D., Cincinnati, Ohio, Chairman; T. C. Gilchrist, M.D., Baltimore, Md., Secretary.

---

[1] There were no meetings held by the Association during the years 1861 and 1862.

Laryngology and Otology.—Wm. E. Casselberry, M.D., Chicago, Chairman; D. Braden Kyle, M.D., Philadelphia, Secretary.

Materia Medica, Pharmacy, and Therapeutics.—W. B. Hill, M.D., Milwaukee, Wis., Chairman; F. Woodbury, M.D., Philadelphia, Secretary.

Physiology and Dietetics.—A. P. Clarke, M.D., Cambridge, Mass., Chairman; Ephriam Cutter, M.D., New York, Secretary.

Wm. B. Atkinson, M.D.,
Permanent Secretary.

THE TWELFTH INTERNATIONAL MEDICAL CONGRESS.

Will be held at Moscow, Russia, August 19–26, 1897.
J. Klein, M.D., President.
W. K. Roth, M.D., Secretary-General.

AMERICAN NATIONAL COMMITTEE.

J. S. Billings, M.D., New York; Frank P. Foster, M.D., New York; Claudius H. Mastin, M.D., Mobile; S. Weir Mitchell, M.D., Philadelphia; Charles A. L. Reed, Cincinnati; George B. Shattuck, M.D., Boston; F. J. Shepherd, M.D., Montreal; George F. Shrady, M.D., New York; W. S. Thayer, M.D., Baltimore.

A. Jacobi, M.D., 110 West Thirty-fourth street, New York, Chairman.

NEW YORK, March 10, 1897.

In a letter dated Moscow, February 14, the Secretary-General, Professor W. K. Roth, communicates the following facts for the information of the American physicians who intend to participate in the Twelfth International Congress, which is to be held in Moscow from August 19th to 26th.

The transatlantic steamship companies refuse one and all any reduction of the usual charges. In their replies, most of which are couched in courteous language (the originals are in the possession of the undersigned), they admit the existence of a trust, or contract, or agreement, which prevents them from lowering their prices; a few are so polite as to express their regrets.

Reductions of fares on Russian railroads are expected shortly. The French, Spanish, Swedish, and Hungarian railroads promise a reduction of fifty per cent.; so do the Italian, for a distance of 500 kilometers; less (down to thirty per cent.) for shorter distances. The Mediterranean lines (Messageries Maritimes, General Italian Navigation Company, Austrian Lloyd) grant from twenty-five to fifty per cent.

The undersigned Chairman is not authorized to issue certificates of any kind in favor of congressists. He will try to ascertain, however, in which way their movements may be facilitated, and may receive a reply in the second half of April. Extracts of papers to be read before any of the sections ought to reach the Secretary-General before June 1st, in order to be printed in the preliminary volume.

A special prospectus containing the final details referring to traveling, lodging, festivities, etc., is promised for a near future. It will be communicated at once to the medical journals and to the press of the country.

A. JACOBI.

CORRESPONDENCE.

TREATMENT OF DIPHTHERIA WITH ANTITOXIN AT THE NEW YORK FOUNDLING ASYLUM.

To the Editor of the MEDICAL NEWS.

DEAR SIR: In the MEDICAL NEWS of March 6th Prof. J. Lewis Smith states that the injurious and negative results of the antitoxin treatment in the New York Foundling Asylum were due to the fact that the serum used was prepared by a French company.

In the last edition of Prof. Smith's valuable text book (page 379) will be found the following statement: "We cannot write so favorably of the use of antitoxic serum in the New York Foundling Asylum. Since a reliable preparation was obtained from the Health Board thirty-one cases were inoculated with the serum. . . . The antitoxin was inserted under the skin on the first day in twelve cases, on the second or third day in seventeen cases, and on the fourth or fifth day in two cases, etc. Results: Recovered, fourteen; died, seventeen; 54.89 per cent. mortality."

The mortality in the Foundling Asylum with the French serum was 45.7 per cent.; with the Health Board serum, 54.89 per cent. These statements from the pen of Prof. Smith show that the unfortunate results of the antitoxin treatment in the New York Foundling Asylum are not due to the employment of an inferior serum. These results do demonstrate, however, that antitoxin is completely useless when used in any severe form of diphtheria. Seventeen deaths in thirty-one cases of diphtheria, that were brought under antitoxin treatment early in the disease, are sufficient evidence of the impotence of this agent in severe diphtheria. On the other hand, sixty-five cases, with only three deaths, is but a repetition of what had happened with other methods of treatment. As good results have been published of numerous other treatments, even bad treatment.

Guttman treated eighty-one cases of diphtheria with pilocarpin, all recovered (*Medical Record*, September 14, 1895). F. Lueddeckens treated eighty-one cases with cyanid of mercury, one death (*Therap. Monats*, 1896, No. 11).

The French serum, which produces such low mortality in Paris, gives in the New York Foundling Asylum 45.7 per cent., and Board of Health serum gives in one series of cases in the New York Foundling Asylum a mortality of 4.6 per cent., and in another series, 54.89 per cent. These wide divergencies in the death-rate admit of but one explanation, namely, the difference in the character of the cases experimented on. In corroboration and substantiation of this explanation, I will cite the variations of mortality in the New York Foundling Asylum before the antitoxin treatment: In 1891 the mortality in this institution was 52.2 per cent.; in 1894, twenty-four per cent. The difference in the mortality in 1891 and 1894 is not due to the treatment; neither is the difference in the mortality in 1895 and 1896 due to the difference in the serum used; but it is the same influence operating in these different years; that is, at one time a high grade, at another time a low grade, of the severity of the disease.

Dr. S. C. Blaisdell of Brooklyn, in a letter to me, states: "I am not using antitoxin at present. My experience with it has been limited to thirty-one cases. I have yet to see a case, either mild or severe, that has been benefited by antitoxin. I am quite certain that it in one case hastened the death of a child where I used it. The temperature of the child (four years old) was before using antitoxin $99\frac{2}{5}$°; in twenty minutes after the injection of 2000 units the temperature rose to 106°. The antitoxin was administered at 11 A.M., child died at 2'clock the next morning. On my own responsibility I will never use antitoxin unless insisted upon by the parents or friends of the patient, they assuming the risk of the result. With antitoxin my death-rate has been thirty per cent., without it about fourteen per cent."

Dr. Wm. L. Johnson of Oxbridge, Mass., writes (*Atlantic Medical Weekly*, February 27, 1897, p. 137): "Could it but really be known how many of the fatal cases that the antitoxin users report were due not to the disease, but to the remedy used, the result would be startling. I have also the notes of thirty cases of diphtheria in private practice, treated with antitoxin and collected from various sources undoubtedly reliable, with the frightful mortality of twenty-three, or nearly eighty per cent."

Professor Smith states that the significance of the term "change of type" of contagious diseases is entirely changed since the discovery of the microbic origin of these diseases, and that the whole subject of "change of type" of contagious diseases should be reinvestigated from the standpoint of modern bacteriology. If the Klebs-Loeffler bacillus is the cause of diphtheria now, it was the cause of this disease a century ago, and the "change of type," so well known in the days of Bretonneau and Trousseau, exists to-day, and has not been changed by the discovery of this bacillus under the microscope. "Change of type" is to-day as it ever has been, inscrutable—even to the bacteriologists. In Trousseau's writings (Vol. II., New Sydenham Society) we find a statement that Bretonneau did not see a single fatal case of scarlatina from 1799 to 1822. In 1824 Trousseau saw with Bretonneau a case of scarlatina which terminated fatally in eleven hours from the onset of the first symptoms. Trousseau adds: "Thus you see that during a quarter of a century scarlatina appeared as an epidemic without showing any severity; then all at once it became changed in its manifestations, and cruelly smote all whom it touched."

JOSEPH E. WINTERS, M.D.

25 WEST THIRTY-SEVENTH STREET,
NEW YORK, March 15, 1897.

Medical Inspectors of Schools.—The New York Health Board has appointed 134 Medical Inspectors of School Children at salaries of $30 a month. Dr. A. Blauvelt, formerly Assistant Chief of the Bureau of Contagious Diseases, was made Chief Medical Inspector, at a yearly salary of $2500.

OUR PARIS LETTER.

[From our Special Correspondent.]

MAX NORDAU'S LECTURES — HYPNOTISM NOW A NEGLECTED PRACTICE IN FRANCE — PFEIFFER'S BACILLUS OF INFLUENZA FOUND IN CONNECTION WITH BRONCHOPNEUMONIA—THE CONSUMPTION OF HORSE-MEAT BY THE POOR.

PARIS, February 17, 1897.

DR. MAX NORDAU, whose permanent residence is now in Paris, where I believe he practises his profession, lectures occasionally at the Institut Psycho-Physiologique de Paris in the rue St. André des Arts, not far from l'Ecole de Médicine. The Institut Psycho-Physiologique is the only place in Paris where regular *séances* in hypnotism are now held, and to the American student familiar with "Trilby" there is an eminent suitableness in the fact that it should be almost on the site where that heroine is supposed to have had her *blanchisserie de fin* in the rue St. Anatole des Arts in the book, that experiments in hypnotic suggestion should still be carried on. But for the ordinary Frenchman that means nothing, for "Trilby" and her history seem absolutely unknown here. Even if you ask for Du Maurier's book at the Bibliotheque Nationale they will bring you Charles Nodier's "Trilby," written in the early part of the century, and can tell you nothing of the other. One is surprised to find, however, that Nordau is not much better known among the French. His lectures attract very little attention and most of his auditors are English and Americans, not always medical students, though the lectures are meant especially for students and are freely open to them.

Some data that may serve as criteria in the judgment of his writings can be gathered from an informal lecture of this kind. He spoke last Thursday on "Psychoses of the Menopause." Nothing new was said, but there was always present that tendency to say half-truths that are paradoxical in an exaggerated form, so as to produce an effect. For Nordau, for instance, there is at the root of all ambition in the male of whatever kind, political, social, or practical, the desire to find favor in the eyes of the female; *i. e.*, a female, some female, though may be unconsciously even to its possessor. Naturally, with as exaggerated an idea of the influence of sexuality as this, the etiology of the psychoses of the menopause and of mental troubles incident to other sexual periods in life becomes merely the consequence of the psychic forces in evolution or involution at these times in the organism. These psychic forces will have serious consequences only on the mental condition of those whose physical organization is not strong enough to stand the strain; in a word, only in the degenerate. Curiously enough, however, while it is his writing on degeneration that has made him famous, Dr. Nordau did not once use the word "degenerate" in his lecture. It is the word that has been consecrated to the description of the groundwork of some of the states which Nordau was describing (by the well-known work of Magnan and his pupils), but he seemed to deliberately avoid the use of it. Perhaps for him degeneration is reserved for that universal downward tendency he has noted in mankind in general, and not the accidental occurrence of beings whose heredity and environment has placed them on a plane below others.

Notwithstanding the seeming pessimistic tendencies of his books, Nordau himself is a very benevolent-looking individual, whose perfectly white whiskers, bald head, and paternal expression, recall the appearance rather of some good old clergyman than of the startling, somewhat anarchistic, innovator in matters of psychological development. He is very much interested in the United States (what foreigner is not who has books to sell!) and recalls with evident pleasure his visit to us during the Chicago Exposition.

I said that the Institut Psycho-Physiologique was the only place in Paris where regular *séances* in hypnotism were given. It is, too, the only place where hypnotic suggestion is put forward as a therapeutic measure of any importance in general practice. The general character of the experiences there are not, I think, calculated to encourage the medical man who may have come to Paris with the idea that the development of hypnotism here in France had placed it on a tangible basis of scientific principles, and had made practical its general medical application. For some time, as Professor Giles de la Tourette, the well-known writer on hysteria, said in a lesson at the Salpétriére not long ago, hypnotism has ceased to occupy serious attention here. It has, in the words of an illustrious compatriot, been allowed to sink into innocuous desuetude. If the dangers, to which patients are exposed by the practice of it, are as serious as Flechsig in his recent inaugural address has made them out to be, it is well that it is so.

A few years ago all the nervous and mental specialists were completely taken up with it. Luys at the Charité, and even the great Charcot at the Salpétriére, were making special studies of it and giving clinical demonstrations of its states and phases, and of its wonderful therapeutic effects. Charcot's work was well done, and some of it remains as the best studies in the subject that we have, but he realized after awhile how fallible and nugatory were scientific conclusions founded on morbid states so protean, so scantily understood, and so little reliable, as those in which the higher stages of hypnotism could alone be developed. He withdrew from the study of it and interest in it faded. Bernheim, at Nancy, is still making exaggerated claims as to its general applicability, and as to the marvellous therapeutic and moral effects of hypnotic suggestion, but these claims are very generally laughed at in Paris. In very suggestible subjects suffering from the severer forms of hysteria it is occasionally used, but one sees suggestion in the waking state more frequently applied.

For the third time within a century, each time in a more alluring form, the subject of the influence of will-power over the wills of others has excited the lively interest of medical men. Each time the subject has sunk back again, not into oblivion, but into a phase of almost complete neglect. Each time something has been gained, but the exaggerated claims of too ardent devotees of the subject have reflected on the study itself and have made its pursuit savor too much of charlatanism. Probably the calmer scientific spirit of conscientious inquiry which will, it is to be hoped, characterize the twentieth century, may enable the next generation (for surely interest in the alluring subject will at some time be aroused for them too) to approach the subject in a more judicial and scientifically disinterested spirit than has been done so far. Meantime expectant students of hypnotism who come to Paris are apt to be seriously disappointed.

A recent report of Dr. Henri Meunier to the Society of Biology seems to show Pfeiffer's bacillus, the influenza microbe, in a new *rôle*, and under circumstances that make its further study very interesting. Dr. Meunier has found it in ten cases of bronchopneumonia in children, in four of which there did not seem to be any connection with *la grippe* in its epidemic form. He thinks that in these cases Pfeiffer's bacillus was the only etiological factor in all of them at the beginning, and in most of them (as pulmonary puncture and repeated blood examinations did not show the presence of other micro-organisms) during the whole course of the disease. The clinical evolution of the disease was that of the ordinary bronchopneumonia, with the exception, perhaps, of even greater depression than usual, and a temperature that was especially rebellious to the action of cold baths.

One wonders if it is not by these cases in children that the disease has been retained as an endemic disease since the great epidemic of 1889. The children, more susceptible because possessed of less vital resistive power, form, it has been suggested, suitable culture media for the attenuated forms of the bacilli. The micro-organism is thus preserved from year to year, and, during specially damp seasons such as this one has been, climatic influences perhaps increase its virulence, the prevalence of bronchial affections give it suitable niduses for growth, and an epidemic such as we have had at Paris once more this year, breaks out. If, as Professor Guiteras thinks, it is this condition of affairs that makes yellow fever endemic in Cuba; why not grippe in the various centers in which it has practically been endemic since its first spread?

The pneumococcus has come to be considered the active pyogenic agent in the purulent lesions secondary to pneumonia, and now comes a report of a case in which it seems to have been primarily and locally pyogenic, without having induced the usual constitutional symptoms.

The case recently reported to the Society of Biology was one in which an open wound had come in contact with some pneumonic sputum. The result was a lymphangitis and purulent infiltration of the neighborhood of the wound. In the pus no other micro-organism but the pneumococcus could be found. This would seem to indicate a hitherto unrealized danger, perhaps, and the necessity of special precautions in surgical and puerperal cases in general practice when pneumonias are being treated.

Occasionally in the outlying districts of Paris one runs across the sign, "Boucherie Hippophagique,"—horse-meat butcher shop. Quite a little horse meat is sold in Paris, though, according to law, it must be distinctly sold as such. Where wages are as low as they are here, and beef as dear (wages are certainly not more than half ours, and beef at least twice as expensive), it is not surprising to find that the poorer classes are ready to take advantage of the chance to get meat cheaply. The meat is darker, less inviting, and when served up usually tougher than beef, but has much the same flavor, and is said to be even more nutritious, weight for weight, than beef. The traffic is regulated very carefully here, instead of being ignored. There has been a growing suspicion for some time in America that horseflesh was being offered as an article of food in various specious forms, such as canned goods and sausages. Owing to prejudice this must be done surreptitiously, and hygiene suffers as a consequence. The more frank, open Parisian method, strikes one as being more commendable.

TRANSACTIONS OF FOREIGN SOCIETIES.

Berlin.

THE NATURE OF OSTEOMALACIA AND ITS TREATMENT WITH OVARIAN EXTRACT—PRESENT POSITION OF INTRAUTERINE MECHANICAL TREATMENT.

SENATOR read a paper on osteomalacia and its treatment with animal extracts before the Berlin Medical Society, January 13th. This is a disease whose etiology is not well understood. It does not appear to be due to a lack of lime salts in the food, as even the poorest diet contains an excess of these salts. Still, certain observers have been able, artificially, to produce osteomalacia in animals by withholding lime salts from their food.

Another theory presupposes a diminished alkalinity of the blood as a result of which the lime salts are dissolved out of the bone, while it is impossible for new salts to be deposited. Experiments along this line in animals have given no definite results.

FEHLING has recently advanced the idea that osteomalacia is due to adverse reflex influences proceeding from the ovaries, and especially affecting the metabolism of the bones. This influence he compares to the influence of the thyroid gland upon the metabolic processes of the body, in certain cases of goiter due to a faulty function of the thyroid. There is doubtless some relation between the ovaries or testicles and the bony system.

With this point in mind, Senator treated with ovarian extract (oophorin) a woman, aged forty-two, who had suffered for ten years with weakness and pains throughout the body severe enough to prevent walking. The bones, and especially the symphysis pubis, presented well-marked deformities. For six weeks the patient received thyroid extract, and after a period of a week, during which time no medication was administered, she was given ovarian extract for eleven days. She lost six pounds during the thyroid treatment, and regained three pounds in the interval, and during the ovarian treatment she lost two pounds. In spite of this fact she improved in feelings and in gait during these periods. Senator attributed this improvement to the medication. Oophorin is easily taken, and does not cause, as does thyroidin, palpitation of the heart, slowing of the pulse, albuminuria, etc., so that he feels justified in recommending its further use.

In the discussion of this paper LANDAU spoke of the success in the treatment of osteomalacia which had followed castration. That a disease should be easily influenced in some cases by the removal of an organ, and in others by the ingestion of its extract, is not at all impossible. In fact, this has been illustrated in the treatment of goiter with thyroid extracts, a subject which a few years ago was as little understood as treatment with ovarian extract is to-day. The benefit of its use in nervous troubles of the climacteric and after castration has been established in numerous instances. The dose should be at least from fifteen to twenty-five grains of the dried material three times daily. It is important to select the ovaries of animals which are neither very young or very old.

VIRCHOW spoke of the different forms of osteomalacia, so different, in fact, that it is doubtful whether they ought to be included under one heading. There is the "red malacia," the "yellow malacia," and a "gelatinous malacia." The first is an irritative process allied to inflammation. The second usually occurs in old people, and is the cause of the brittleness of the ribs which is often met with. It may often affect the extremities. These two forms, of course, have nothing in common. The "gelatinous" form is of especial interest because a peculiar albuminous substance, which exists in these cases in the bones, has been shown by Bence-Jones to exist in the urine. This albuminate is not found in normal bone nor in the bones of those suffering from "red" or from "yellow" malacia. Attention has been called to the removal of the lime salts from the bone, and many experiments have been made to determine what special acid was responsible for this decalcification. This supposition is entirely unnecessary. The carbonic acid of the blood is of itself quite sufficient to remove the lime salts, if once the power of the bones to cause their deposition is taken away or lessened. The primary cause of osteomalacia is probably a neurotic one by which this power of the bones to fix the lime salts is weakened. However, it would be going too far to say that this is the cause in all cases of this disease.

At the session of February 3d, SIMONS said that intrauterine mechanical treatment had been too hastily and unjustly condemned. Treatment with a sound is of service in (1) cases of delayed development; (2) cases of atrophy; (3) cases in which an angular anteflexion exists. Chlorotic girls, for instance, in whom the ovaries are well-developed, or over-developed, while the uterus remains aplastic, suffer from dysmenorrhea and amenorrhea on account of this lack of proportion between uterus and ovaries. If a sound is passed and external massage is lightly made upon the fundus three or four times during the week preceding menstruation, the pain can be greatly diminished. Another benefit from intrauterine treatment occurs in married women with long cervices and sharply anteflexed corpora. This is a frequent cause of dysmenorrhea which continues throughout the menstrual period. In Simons' experience in these cases the use of intrauterine pessaries quickly and completely straightened the canal of the organ. For the accompanying sterility the cervix should be incised bilaterally and posteriorly some weeks before the introduction of the pessary.

LANDAU took exception to these opinions of Simons, claiming that the increase in thickness of an aplastic uterus which followed the measures indicated was due not to a normal stimulation of the organ, but to an inflammatory reaction brought about by the foreign bodies. The introduction of these into the uterus is capable of setting up salpingitis, or pyosalpinx, or abscesses, and may cost the life of the patient.

CZEMPIN said that the inflammation of one sort and another which followed intrauterine mechanical treatment before antiseptics were known does not follow such treatment now if proper precautions are employed. In his opinion, the use of an intrauterine pessary is not only safe but beneficial in such cases of faulty development as Simons referred to. Such cases are not cured by curetting, while they may be cured by the methodical treatment by sounds.

London.

TYPHOID BACILLI IN THE URINE—DEAFNESS FOLLOWING DISLOCATION OF THE JAW—EFFECT OF CASTRATION IN THE ADULT.

At a meeting of the Royal Medical and Chirurgical Society, held February 8th, **HORTON-SMITH** read a paper on *typhoid bacilli in the urine of patients* suffering from typhoid fever. In sixty-one undoubted cases of typhoid fever, careful investigation showed that typhoid bacilli were present in only eight. They were never present in the early stages of the disease, and therefore the diagnostic value of this test is small. In some of the published cases in which typhoid bacilli were said to exist in the urine, sufficient care was not taken to distinguish this germ from the bacterium coli commune.

At a meeeting of the Odontological Society of Great Britain, held February 1st, **BOWDEN** narrated an interesting case of *deafness following bilateral dislocation of the jaw.* The patient, a female, aged thirty-seven, while under the influence of nitrous oxid gas, had the three left lower molars removed. On regaining consciousness it was discovered that there was a bilateral dislocation of the lower jaw, which was easily reduced under the further administration of the anesthetic. Three weeks later the patient was found to be absolutely deaf in the left ear, the deafness being due, apparently, to the violent wrench of the jaw, which, by pulling on the cartilaginous meatus and tympanum, had set up an inflammation which had extended to the labyrinth.

At the session of the Pathological Society, held February 16th, **SHATTOCK** described *the histological characteristics of testicles removed in the radical cure of hernia.* The patient, aged forty-two, presented the usual congenital conditions resulting from extreme hypospadias with cleft scrotum. The testicles were in the inguinal canal and undersized. They did not contain spermatozoa or spermatoblasts. The question of an *internal secretion of the testicle was discussed.* It is unfair to argue from the condition of the child after castration to that of the adult. One result of double castration in the adult is obesity. In certain cases, also, marked mental disturbances follow double castration. These and other questions may possibly be answered by a study of the cases in which the testicles have been removed for enlarged prostate. Most of these patients are rather old for this study. This method of treatment is giving way to the division or partial excision of the vas deferens. Hence, in this more modern operation, while the power of the testicles to produce sperms is put an end to, its "internal secretion" continues. Therefore, a comparison of cases operated upon by these two methods ought to throw considerable light upon the question of after-effects of castration.

BOYD cited a case of a man from whom he removed the testicles for tuberculosis, one some time after the other. Removal of the first was followed by little result, but after the removal of the second the patient became mentally childish, was unable to control himself, and wept without being able to explain why. These symptoms wore off in time. In the second case, that of the older man, the only change observed was obesity. The benefit which sometimes follows in carcinoma of the breast by oophorectomy is noteworthy as pointing to the formation of some internal secretion by the ovaries.

At a session of the Clinical Society held February 12th, **PAGET** called attention to the voracious hunger and thirst after injury or disease of the brain. He collected notes of fourteen cases pointing to the existence of special centers of hunger and thirst close to the centers of speech. Eight of the fourteen patients suffered from a voracious appetite for solid food without much thirst; three suffered from both hunger and thirst, and three had thirst alone. In not one of these cases was the primary injury or disease fatal. With regard to treatment, no harm came in any of these cases from allowing the patient to eat and drink all he chose.

SOCIETY PROCEEDINGS.

NEW YORK CLINICAL SOCIETY.

Stated Meeting, held January 22, 1897.

The President, **ANDREW J. MCCOSH, M.D.**, in the Chair.

THE SURGERY OF THE FACE.

DR. ROBERT ABBE made some remarks on this subject, illustrating them by numerous photographs.

Hare-lip.—Commenting on a series of hare-lip cases, he said that much had been done toward improving this operation during the last twenty-five years. The old Malgaigne operation has been very generally abandoned. In the mild cases of this deformity, there was no occasion for any specially devised operation; all that was needed was a simple plastic operation adapted to the individual case. But in the more serious deformities, *e.g.*, when the nostrils are flaring and the intermaxillary mass is attached to the nose, or where the gum on the prominent side protrudes far out from the end of the nose—no single, simple procedure could be described for any case. In the last few years it had been his practice in operating upon the lip to pare off and sacrifice a portion of the red lip on the best side, and then bring down on the other side a mass to make the center of the lip. It was necessary, however, to take into consideration the displacement of the tip of the nose to the side opposite the cleft; it had to be brought forward with considerable force, and held there. He had recently adopted the plan of inserting two heavy Hagedorn needles, one into the skin under the columna, and the other in the alæ nasæ at the side which rises, driving them in through the lip to the bone. This kept the parts absolutely in place. He was of the opinion that a great deal had been accomplished by this measure in addition to the usual suturing. In double hare-lip it was not always easy to get a good result. The Hagedorn operation was useful here.

Nevus of the Face.—He said that he had treated many scores of cases of nevus of the face. The best treatment consisted in the use of an ordinary large cambric needle, or a hat-pin, heated to a red heat, and then plunged into the tissues of the nevus *at a black heat.* The insertion of the needle at a black heat had much to do with securing a good result. Punctures should be made in this way all over the tumor. There was no bleeding whatever, and the case was usually cured in three or four operations.

Epitheliomata of the Face.—These constitute a serious blemish, and, if neglected, produce enough erosion to become a menace to life. The manner of their removal varies with different surgeons. While not denying that caustics often produce a cure, he would say without hesitation that the knife was in every way superior. Thiersch grafting, combined with the use of the knife, furnished an opportunity for going much more wide of the disease. One of the photographs showed an epithelioma so extensive that it became necessary to enucleate the eye, and to expose the dura mater for a considerable space. Skin grafts were laid upon the dura mater, the bone, the fat of the orbit, and upon the muscle. It was found that these grafts grew upon all these various tissues. It was now two years since the operation, and there was no sign of recurrence. Paget had called attention to the fact that if a "wen" of the scalp were allowed to break, it would become an eroding epithelioma of the scalp. He called these "exploding cysts." Excision of cancers of the lip by a V-shaped incision is one of the most satisfactory of all operations. In the great majority of cases there is no recurrence. Photographs were shown of three cases of extensive cancer of the lower lip, in which the disease had been excised thirteen years ago. They had been seen within a month, and there was still no recurrence. Another case was one which had been faithfully and skillfully treated by an eminent practitioner by caustics, but only with the result of leaving an extensive sloughing area. It was excised about twelve years ago, and had not recurred.

Trifacial Neuralgia.—In the first case reported, the man had suffered from inveterate trifacial neuralgia for many years. He was cured by making an incision into the cheek, breaking through the posterior wall of the antrum, and cutting off the second branch at the foramen rotundum. The operation was not difficult, and the result was good, although a scar was left upon the cheek. In another case, he had operated upon a woman of sixty-six, a year and a half ago, doing Hartley's operation. She had suffered terribly from tic-douloureux for many years. The operation consisted in removing a temporal osteoplastic flap, dividing the branches of the nerve at the foramen ovale, and evulsing them from the Gasserian ganglion. She recovered perfectly under this operation. In another case, more recently operated upon by this same method, he had been unable to bring out the nerves from the ganglion, and had therefore covered the foramen with sterilized rubber tissue, interposed between the Gasserian ganglion and the divided nerves. The patient had had no pain since the operation.

Scars from Burns.—In one instance he had attempted to transplant hair-growing scalp, but although great care was taken to remove the uninjured hair bulbs in the flap, no growth of hair took place.

Depressed Nose.—In a case of marked disfigurement of the face from the kick of a horse, jamming in the nose completely, an incision was made, about an inch long, between the eyes, and the flap drawn up. Then a bone flap was chiseled from the forehead, turned upside down, and fastened in such a way as to make a very fair bridge to the nose.

Depressed Fracture of Skull—Followed by Fits.—In a case of this kind, the operation showed the brain and dura mater adherent. They were separated, a piece of sterilized rubber tissue placed between the two, and the dura mater sutured over it. He had followed this case for a long time, yet there had been no return of the fits.

In another case, treated in the same manner, there had been daily fits before operation, yet up to the time when last seen, a year and a half after the operation, there had been no return of these fits.

Smallpox Pitting.—A young girl, who was terribly disfigured by smallpox pits, was etherized, the skin thoroughly sterilized, and with a sharp knife all the islands of skin between the pocks were shaved down to the level of the pock marks. The surface was then dressed as after skin grafting. The result was a thin, smooth, white cicatrix, and a very great improvement in her appearance.

Fracture of Nose—Emphysema of Orbit.—A man after sneezing violently suddenly developed emphysema of the orbit. The day before he had had a fall, but had thought nothing of it at the time. Of course the fall had fractured the nasal bones, and the sneezing had caused the passage of air through to the orbit. Dr. Abbé said that almost all broken noses were capable of repair, with good result, if treated early, and often even when not treated until late.

Tumor of Skull—Growth Arrested by Partial Excision and Use of the Erysipelas Toxins.—A case was reported of a rapidly growing tumor of the skull in the temporal region, occurring in a baby. The case seemed desperate, but he had operated in the hope that it might be an enchondroma. On chiseling through the skull the tumor was thought to be a very dense sarcoma, growing internally as well as externally. A portion was excised, and Dr. Dunham reported it to be an endothelioma. The child was given the erysipelas toxins. The patient had continued to grow and thrive, but the tumor growth had been arrested. It was the only case in which he had observed any apparent effect from the toxins. Judging from the former rapidity of growth, this child should have been dead a year and a half ago.

Mucocele.—In this case the ethmoid and sphenoid bones were dilated by a large mucous cyst. A wide incision was made in a corner of the orbital cavity. On introducing the finger it was found that the mucocele invaded the cranial cavity. The contents were evacuated and the cyst packed with iodoform gauze. It was allowed to granulate for a time, and then it closed.

Ankylosis of Jaw.—In one case he had excised the neck of the condyle, with a good result. If one cuts down to the point where the bone is narrow, the result will be good. Less than this is likely to result in ankylosis again.

Anthrax.—In this case there was under the jaw a raised, oval patch of purplish color, looking like a very virulent vaccination mark. At the time the photograph was taken the temperature was 103.6° F. Anthrax bacilli were found in the blood and in sections from the diseased area. The latter was excised widely, and at first the patient improved in every way, but he died, four days later, of an extension of the affection.

DISCUSSION.

DR. J. H. EMERSON said regarding the subject of Paget's exploding cysts, that he knew of a lady, ninety-one years old, in whom a wen on the shoulder-blade had ruptured and left a fungating ulcer. The patient had refused treatment at the time, and when seen by Dr. Weir long afterward, his diagnosis had been that of epithelioma. Six months later, or last October, she had developed symptoms of cancer of the stomach, and had died of this disease a few weeks ago.

DR. E. B. DENCH referred to a case in which he had restored an external auditory meatus which had been obliterated by five mastoid operations. The patient was a young man who had suffered from suppurative inflammation of the middle ear, involving the mastoid. When seen by him, there was distinct evidence of pus in the mastoid, and the external auditory meatus was closed. He had done a Schwarze-Stacke operation, throwing the auditory canal, tympanic cavity, and cells into one cavity. No flaps were available, so the wound was left open for about two weeks. The canal was gradually dilated by passing strips of gauze through the narrow opening. The patient was then etherized, and the ear split upward and posteriorly through the entire thickness, the integument was dissected off from the anterior surface of the concha, and the cartilage and overlying cellular tissue cut out. On pulling the ear forward, a small portion of the inferior wall of periosteum lining the bony meatus was found. This was caught and sutured to the anterior flap. The posterior margin of the original wound was then dissected off, and sutured, and at the completion of the operation, the meatus was patent and completely restored, It was possible to cut off the entire auricle without causing much disfigurement. He had operated upon four or five cases of malignant disease of the auricle, and in each case he had been surprised at the freedom from recurrence.

DR. GEORGE WOOLSEY said that he had recently operated for the second time upon a man who had had several injuries to the head, which had caused epilepsy. Replacing the bone flap did not seem to act well. Accordingly, after excising the thickened and adherent dura, some gold-foil had been inserted. The patient had been much benefited, but had had occasional nocturnal fits. At a recent operation he had had an opportunity of seeing the gold-foil, and had found it embedded in a thick, artificial dura, which was adherent to the brain beneath and the scalp above. The foil had been sterilized between the sheets of paraffin paper, and it had been quite difficult to completely remove this wrapping at the time of the first operation. At this second operation, a piece of celluloid had been substituted.

He had been much interested in the case of deformity from smallpox pits. He had shaved down "rum-blossoms" after this method, with good results.

DR. D. BRYSON DELAVAN reported the case of a young man of twenty-five, whose life had been prolonged by two formidable operations for the removal of an angiosarcoma of the nasopharynx; another was an extensive epithelioma of the face, which had been cured by a flap operation and extensive skin grafting; another was a case in which the supraorbital branch of the facial nerve had been extirpated with the result of relieving an intense tic-douloureux. This was two years and a half ago, and there had been no return of the trouble. He asked if Dr Abbé thought the hot needle was preferable to the electrolytic method for treating nevus. Dr. Abbé replied that even with the very finest needle, if the electrolysis were effective, there would be more scar than when the hot needle was used. Dr. Delavan said that scrapings and caustics were very commonly used in epitheliomata, yet he felt, with Dr. Abbé, that the knife was vastly superior. He had been greatly interested in the report of the case in which the toxins of erysipelas had possibly effected a cure.

DR. F. TILDEN BROWN asked if, in the case of loss of the alæ nasæ, the taking of the flap from the arm had given as good a result as would have followed the use of a flap from the face.

DR. ABBÉ, in closing, said that the flap from the arm gave at first a beautiful result, but after a time it was found that its capillary circulation was not the same as that in the nose, and that therefore it presented a more waxy appearance. He thought it would have been preferable to take a flap from the cheek, in spite of the scar that would have resulted. He had removed a number of sarcomata of the upper jaw, with very satisfactory results. The disease was usually confined to the antrum and its walls, and hence could be thoroughly removed by excision of half of the upper jaw. In these cases there had been no recurrence for a long time.

GLANDULAR SWELLINGS.

DR. GEORGE M. SWIFT reported a case of a girl of fourteen, who had had a moderate fever for a few days, followed by a swelling of the post-cervical glands. The swelling had subsided in two or three days, and after another interval of about the same length a similar swelling had appeared on the opposite side, accompanied by fever.

DR. WALTER MENDELSON said that he had seen quite recently a precisely similar case, except that so far it had been confined to one side.

HIGH TEMPERATURE IN AN INFANT FROM THE USE OF HOT BOTTLES.

DR. G. M. SPAULDING reported the case of an infant, three days old, whom he had directed to be kept warm, as it was quite feeble. At 8 A.M., the rectal temperature was 101.5°; at 12 M., 100°; at 6.30 P.M., 107.4° F. At this time the child had a peculiar cry, and was evidently in distress. The temperature of the room was 72° F., but the child was lying near the steam radiator, and was kept artificially warm by a hot-water bag. The artificial heat was at once taken away. At 9 P.M., the rectal temperature was 102°, and at 10 P.M., 100° F. The baby had shown no depression after this high temperature; it had not lost weight; and now, when twenty days old, it was steadily improving in every way.

DR. L. EMMETT HOLT said that he had seen several temperatures of this nature, one or two after surgical operations, thus making the condition all the more perplexing. He thought the prominent feature in these cases was that the temperature was entirely out of proportion to all the other symptoms.

SUPPURATION OF THE ANTRUM; RECOVERY WITHOUT OPERATION.

DR. D. BRYSON DELAVAN reported a case of suppurating disease of the antrum, cured without operation. The patient, a young married lady, had come to him about two weeks ago, having for three weeks been troubled with the symptoms of this disease. By transillumination the diagnosis of suppuration of the antrum had been easily established. The maxillary opening was occluded by thickened tissue in its neighborhood, and at a certain hour every morning there was a muco-purulent discharge. The parts were cleansed by him on alternate days, the patient meanwhile using a cleansing wash, and taking a course of tonic treatment. To-day, by transillumination, the antrum was found entirely free from disease, the symptoms had entirely subsided, and the case was cured. He had seen a similar result in a young man of thirty-five, hence the importance of watching these recent cases and treating them with the hope of avoiding operation. The operation was simple enough, but the after-treatment was troublesome and very unpleasant.

A PECULIAR CARDIAC NEUROSIS.

DR. HENRY C. COE said that he had seen two peculiar cardiac cases within a week. The condition had been very alarming, but the good appearance of the patients had led him to give a favorable prognosis. The first was a curettage for an incomplete abortion, performed at night, the patient's temperature being 104° F., and the pulse 120. There was considerable hemorrhage after the operation. The pulse suddenly became very weak, although very little anesthetic had been taken. Notwithstanding this, the respiration was not much disturbed, and the patient's color was good. She responded quickly to the administration of nitroglycerin and strychnin. The other case was quite similar, except that her pulse remained weak and rapid for about eighteen hours. It was a woman who had been confined normally, but had been kept in bed for two weeks because of a history of having had phlebitis after a former confinement. Nothwithstanding this precaution, she developed phlebitis on getting up, and had been accordingly sent back to bed. Suddenly the pulse became very rapid and thready, but she said she felt well, and she certainly looked well. She did not respond satisfactorily to any of the usual stimulants—strychnin, nitroglycerin, and camphorated oil—but the next morning the pulse was 84, and has remained so since then. The patient was not hysterical, and there had been no previous attack of this kind.

DR. FRANK W. JACKSON said that these cases should be classified as essential tachycardia—a condition not very uncommon, yet about which we know very little.

TUBERCULAR MENINGITIS WITH PECULIAR FEATURES.

DR. C. A. HERTER reported the case of a patient who had had tuberculous joint disease, and who had been suddenly attacked with severe headache and vomiting. The same day he had become delirious and then comatose, and had had repeated convulsions. Death had occurred within three days after the onset of the headache. The autopsy showed a typical tuberculous meningitis. One interesting point was the extremely small amount of exudation. Another interesting feature was the existence of a solitary tubercle in the left lobe of the cerebellum, about three-fourths of an inch in diameter, which had caused no symptoms during life. He said that he had seen a solitary tubercle in about the same position in two or three other cases where there had been nothing pointing to a cerebellar condition.

DR. H. M. BIGGS said that he was reminded of a case of anthrax meningitis. There had been an infection at the wrist, from which the man had apparently recovered. He suddenly developed headache, delirium, and a temperature of 107° F., and death occurred in less than fifteen hours. The autopsy showed a very extensive sero-hemorrhagic exudation, and pure cultures of the anthrax bacillus were obtained from the brain. Cultures made from the skin, heart, and various other parts of the body were negative.

TRANSPOSITION OF THE ABDOMINAL VISCERA.

DR. FRANK W. JACKSON said that he had recently seen a German, forty-five years of age, who, for seven years, had had numerous attacks of vomiting of blood from the stomach, with an occasional discharge of bloody stools. Coincident with these attacks there had been extreme anemia. Physical examination showed no evidence of liver dulness on the right side. There was a fair area of dulness corresponding to the spleen. Considerably to the right of the median line, and extending to the vertebral column on the left, was a mass projecting some distance below the free border of the ribs, and upward to the fourth space. This man said that Nothnagel had diagnosticated his case as one of transposition of the viscera below the diaphragm.

ORIGINAL ARTICLES.

THE ORTHOPEDIC TREATMENT OF SPASTIC PARALYSIS IN CHILDREN.[1]

BY SAMUEL KETCH, M.D.,
OF NEW YORK;
PRESIDENT OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

A CLASS of cases which sooner or later require orthopedic measures for the relief of deformity, have been variously called spastic paralysis, Erb's paralysis, paralysis with rigid muscles (Adams), pseudotetanoid paraplegia (Seguin), etc., etc. It will not be within the province of this short paper to enter into the pathology of this affection, which belongs to and has been studied by the neurologist. Its object will rather be to evoke a discussion as to its treatment from the standpoint of the orthopedic surgeon, as in some of the mooted questions, there is still a wide difference of opinion. Clinically, these cases present themselves to the orthopedic surgeon at various epochs of the disease, and at these different times, the manifestations are such that the different conditions should be the basis for their appropriate treatment.

For clinical purposes these cases may be divided into three classes: (1) Those where the mentality is practically nil (idiots); (2) those where the mentality is diminished; (3) those where the mentality is normal or only slightly interfered with.

The characteristic deformity of spastic paralysis is due to a contraction non-permanent in character, and where the element of irritability is always present in a greater or less degree. This irritability is manifested by the increased reflexes, and by the incoordination of muscular movement, resulting in the different deformities. All who are familiar with these cases, and have had the opportunity to observe them for an extended period of time, have seen at various stages of the disease a variation both in the character and location of the deformities produced. Hence it is that treatment should naturally differ, according to the time at which a case presents itself to the orthopedic surgeon.

The treatment may be classified as (1) general, (2) mechanical, and (3) operative.

The general treatment, in addition to the limited medicinal agents at our convenience, is comprised in the employment of mental training, electricity, and massage. The former, while necessary and important during the whole course of the disease, is one which belongs to the province of neurology, and need not be elaborated in detail here. Its best results are shown in cases where it has been continued systematically in schools for feeble-minded children, and under competent direction. Theoretically, the application of any remedy which would increase peripheral irritation, would certainly be contraindicated in an affection whose chief characteristic is one of exalted reflexes. Thus faradism, which has been extolled, or any interrupted current, should not be used. Personally, I have never seen any advantage from the use of electricity in any form, but if used it certainly should be for its "sedative" qualities, in the form of a constant or stable current.

Massage, in the ordinary sense of the term, except as a means of keeping the muscles in good general condition, has, as a remedial measure for the relief of deformity, no especial value in this class of cases.

Purely orthopedic measures are represented by a consideration of the mechanical and operative methods, and a discussion of these will be the object of this paper. The mechanical devices are embraced under those whose object is either improvement in locomotion or cure of the deformities.

It is the common experience of the orthopedic surgeon to have children afflicted with spastic paralysis brought to him with the request that some apparatus be applied to improve locomotion. It is in this connection that the clinical division which I have separated into three types becomes important as a basis, both for selection of apparatus and for operative measures. Thus it would be manifestly absurd, where incoordination and spasm were extreme, as occurs in the idiotic class, to burden them further with apparatus which they neither have the will-power nor proper muscular strength to support. The proper use of apparatus in these cases is only applicable to those where mentality is slightly or not appreciably affected. Here we can by apparatus prevent the increase of deformity by judicious use of supraincumbent weight and the approximation of the deformed parts to their normal position. I have deemed it unnecessary to enter here into an extensive description of the symptoms of spastic paralysis. All of you are familiar with the "scissors gait," the characteristic "Equino varus," and the various spastic contractions which produce the different deformities of both upper and lower extremities, interfering with proper use of both. Contractions of the upper muscular part of the body are rare, as compared with those of the lower. The greatest number of cases are comprised in the two classes, adducted thighs and elevated, inverted feet. Where both of these conditions are present it will be seen that no apparatus can in itself be efficacious for purposes of locomotion. Another object, however, is always to be borne in mind in the use of apparatus, and that is the maintenance of the normal position of parts. It is easy enough to obtain good position in these cases, but it requires unusual care and supervision to maintain it. No apparatus should be applied, in my opinion, where this skilled supervision is lacking, and also a definite knowledge on the part of those having the home care of the case as to the object of the apparatus. In the comparatively rare cases of this affection, where only single muscular groups are involved, as in unilateral, or even bilateral, clubfoot, more can be accomplished by apparatus, both as regards locomotion and cure. Here it is, however, that the question of the time when these cases are seen becomes important. As before stated, the deformities produced by spastic paralysis differ in character at various epochs of the malady. Thus it has been observed that many of these cases showing almost complete helplessness in infancy have attained to a condition later in life where comparative activity was present. In most all of the cases, except the completely idiotic, there is a progressive tendency toward improvement in walking. Clinical observation shows that as the cases approach adolescence the "irritability" lessens and the contractions assume a more fixed type. The best use of apparatus is obtained as the spasticity approximates the minimum. It is not the object of this paper to extol any special apparatus, but it is hoped sufficient has been stated as to the indications for the employment of such mechanical procedures as will enable the surgeon to ameliorate the distressing deformities of the disease.

---

[1] Read before the Orthopedic Section of the New York Academy of Medicine, February 19, 1897.

Before dismissing the subject of the mechanical treatment, it would be well to speak of the question of stretching of muscles affected by spastic paralysis. This may be done either by manual exercise, applied to the different deformities, or by the use of, in the clubfeet, mechanical appliances. Here, again, it is possible by these means to maintain the parts in good position and prevent further progress of distortion, and as an adjuvant, there can be no question as to the utility of this procedure.

A consideration of the operative treatment will include tenotomy, myotomy, and also the questions of circumcision and cerebral surgery. Very little will be said of the latter procedure, as besides Bradford's and Morton's cases, we have as yet no data sufficient to uphold it in the surgical treatment of these cases.

Tenotomy and myotomy are recognized measures for the relief or cure of the deformities of spastic paralysis. The former, however, is the one most frequently used, and will occupy our attention.

There can now, in the light of clinical experience, be no question as to the utility of tenotomy, open or subcutaneous, in properly selected cases. I use the term "properly selected cases" advisedly, as I believe that many of the indiscriminate tenotomies done for the deformities of spastic paralysis are ill advised and unbeneficial. The antagonism of many neurologists on theoretical grounds is probably due to the results seen, in many of these cases, where the operation was performed irrespective of the conditions present or the after-treatment. Again, I believe that the irritability, general and local, should, in connection with the time, be a guide for the performance of the operation. Thus, the greater the irritability, or in other words, the greater the spasm, the less favorable is the result apt to be. If we are in position to so place the parts deformed, where we can control the deformity, it would seem rational to delay the performance of tenotomy until such time as the spasm approximates the minimum, and where the deformity becomes more fixed in character. In a large service, some years ago at Randall's Island Hospital, where there was a separate building for idiots, spastic cases were common. I operated in many of these cases, and although the after-treatment was in most of them carefully carried out, my success was not in accord with what I had been led to believe by the writings of Rupprecht and others. He it is who is responsible for the statement, that many of these cases after tenotomy, not only showed cure of the deformities, but also great improvement in the mental condition. I have not been able to satisfy myself as to the truth of the latter proposition. It is quite natural to believe, however, that many of these cases, by their being brought into contact with new things, by being better able to use their muscular sense, by seeing, touching, and walking, should apparently evince a better mental status.

The danger of relapse after tenotomy is, I think, much greater in this class of cases than in either the congenital or acquired clubfoot. We are here dealing with a "constant current of spasm" so to speak, which by operation is only checked for the time being, unless the after-care is very thorough and complete. If this is not carried out many of these cases will be in a worse condition than before operative measures were resorted to. Thus, while I am in favor of tenotomy as a means toward the rectification of the deformities of spastic paralysis, I would again call attention to the question of time and amount of irritability as guides to the proper selection of cases for the performance of either tenotomy or myotomy.

I shall not speak of circumcision except as a means, in a certain number of cases of this affection, of removing reflex disturbance of the nervous system. Dr. Sayre, whose name is connected with this operation in cases of spastic paraplegia, uses it in this sense, and not as a cure for deformities the result of either organic, brain, or spinal lesions. Many of these cases are undoubtedly benefited in a general way by the removal of any reflex disturbance which tends to keep up the general condition of spasm.

In conclusion, I hope these remarks, which are based on purely clinical grounds, will be of service in establishing some landmarks in the question of the relief of one of the most distressing class of cases with which the orthopedic surgeon has to deal.

THE PHYSIOLOGICAL ACTION AND THERAPEUTIC USES OF YEAST NUCLEINIC ACID, WITH SPECIAL REFERENCE TO ITS EMPLOYMENT IN TUBERCULOSIS.

By VICTOR C. VAUGHAN, PH.D., M.D.,
OF ANN ARBOR, MICH.;
PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN, AND DIRECTOR OF THE HYGIENIC LABORATORY.

(Concluded from page 366.)

CASE LIII.—Mr. G., aged thirty-two, of Detroit, was examined July 5, 1895. There was no family history of tuberculosis. Both parents were then living, and his two brothers were healthy, active business men. The patient has been for some years given to the abuse of alcoholic drinks. Within the preceding twelve months his weight has fallen from 170 to 120 pounds. Examination showed extensive involvement of the lungs and larynx. Both apices were retracted. There was a large cavity on the left side under the third interspace. Crepitant râles were heard over the upper half of the right lung. Moist râles were heard posteriorly both above and between the scapulæ. The expectoration was abundant, purulent, and full of bacilli. Considering the condition of his lungs, this is in some respects one of the most satisfactory cases which has come under my treatment. During the first two months I could not see the slightest evidence of improvement. Indeed, the disease steadily progressed. The afternoon temperature frequently went as high as 103° F, and the weight slowly diminished, but early in September, 1895, the appetite improved, the cough became much less continuous, the sputum lost its purulent character, and in several samples no bacilli could be found. This would be true sometimes when all the sputum raised in twenty-four hours was collected and examined. At other times a few bacilli could be found. This condition of the sputum continued as long as the patient was with me, which was until December 21, 1895. There was also marked improvement in the physical signs. The cavity remained, and there was bronchial breathing over both upper lobes, but there were no râles. Dr. McClintock has examined this patient (October, 1896), and reports that there has been further improvement, and that he is now using the nuclein again.

CASE LIV. — Miss B., aged twenty-seven, of Owosso, Mich., a stenographer, was examined July 9, 1895. Her father died at forty-five from some stomach trouble. Her mother is living, and apparently well, but earlier in life she had pulmonary hemorrhages. A sister of her mother and a brother and sister of her father died of consumption. Miss B. has been "out of health" for three or four years, but did not begin to cough until four months ago, when she had an attack of influenza. Since then she has been coughing and raising abundantly. She had heavy night sweats, and the menses have been suppressed for some months. There was at least one cavity in the left lung, and there was bronchial breathing over the upper lobe on the right side. The patient remained under treatment with me until about October 1, 1895, when she went to Talapoosa, Ga., where the nuclein injections were continued by a very intelligent physician. The result in this case conforms to the general rule for this class. There was temporary improvement, gain in weight of about ten pounds, restoration of the menses, diminished cough and expectoration, and then under the continued use of the nuclein, retrogression and gradual failure. She died in August, 1896.

CASE LV. — A. B., aged twenty-one, farmer, Hersey, Mich. One brother and one sister had died of consumption within the past five years. Patient was with both brother and sister during their illness. He had lost about twenty pounds during the last year. Right lung: Bronchial breathing throughout upper lobe; crepitant râles in the superior axillary region. Posteriorly a large cavity was detected above the scapula. There was bronchial respiration between the scapulæ. Left lung: Bronchial respiration over upper lobe; crepitant râles through the lower part of the lung and throughout the axillary area. Bubbling râles were heard posteriorly.

There was an ischiorectal abscess, which had been opened by his physician in March, 1895, and which at the time of my examination was discharging freely. This abscess was opened more freely and dressed with nuclein and iodoform, and healed completely within one month. This patient remained under treatment until October 1, 1895. His lungs showed some improvement in physical signs, and the weight increased four pounds. The temperature was not materially altered, that for 4 P.M. averaging 100° F. during the first and last weeks of treatment. When he went home, October 1, 1895, I gave him a prescription for capsules, containing one grain each of iodoform and sulfate of quinin and one-sixtieth of a grain of strychnin sulfate. I have been unable to obtain further information concerning this patient.

Case LVI.—Miss W., aged twenty-five, of Ann Arbor, was examined July 10, 1895. Her mother died five years ago of consumption. Miss W. was with her mother during the illness of the latter. Her mother had two sisters, both of whom died of consumption. Miss W. had not felt well since the death of her mother. She had lost ten pounds since June 1, 1895. She had been having night sweats for two months, and felt "flushed and hot" every afternoon. The cough was slight, and the sputum consisted of glairy mucus, containing a few tubercle bacilli. The only abnormality which could be found in the lungs consisted of crepitant râles in the right apex. The afternoon temperature ran from 99.5° to 100° F. The râles disappeared, and no germs could be found after three weeks of treatment. The injections were continued until October 1, 1895. The patient has shown no signs of disease since, and raises nothing.

Case LVII.—Mr. R., aged thirty-two, of Toledo, O., was examined July 10, 1895. He had no family history of tuberculosis, but there was sufficient evidence of direct exposure to the infection. A young man with tuberculosis had worked for many months in his office. This clerk had coughed and expectorated freely, and there had been no attempt to disinfect the sputum, and it was R.'s recollection that the clerk had expectorated on the floor. This was some five years before he came to me. He had known himself to be tuberculous for about two years, and had spent a part of one winter at Asheville, N. C. There were numerous small cavities in both upper lobes. The afternoon temperature went as high as 101° F. The treatment was continued until the middle of September, 1895, when he went to Utah for permanent residence. I have not heard from him since. There was a slight gain in weight during treatment, but no essential improvement in physical signs.

Case LVIII.—Charles M., aged seventeen, of Northfield, Mich., was examined August 13, 1895. There was no history of tuberculosis in the family, and no evidence of direct contagion. In March, 1895, he began to cough, and from that time to the date of examination he had lost fifteen pounds in weight. The amount of sputum raised daily averaged about two ounces. There were a few bacilli. Moist râles could be detected in the right subclavicular area. No other abnormality could be found. The average temperature for three days before beginning the treatment was at 8 A.M. 99°; at 12 M., 99.4°; at 4 P.M., 100°; and at 8 P.M., 98.6°. The treatment was continued until the middle of September, 1895. By this time the temperature had become constantly normal. The cough and expectoration had ceased, and he had gained ten pounds. He remains well, and has no cough.

Case LIX.—Miss L., aged twenty-eight, of Detroit, was first examined August 13, 1895. One sister had died of consumption at the age of twenty, eight years ago. Miss L. had been with this sister during her illness. She had been coughing for three years, and was in the last stages of the disease. There were numerous small cavities in both upper lobes. The afternoon temperature went as high as 102.5° F. The treatment was continued for eight weeks, and without effect on the progress of the disease. She died about three months later.

Case LX.—Mr. C., aged thirty-seven, of Amsterdam, N. Y., a druggist. There was no family history of tuberculosis and no evidence of direct contagion. Patient had influenza six years ago, and has been coughing and expectorating ever since. There were cavities in both upper lobes. Treatment was given for two months without benefit. He died the last of December, 1895. During the last week of his life there was involvement of the meninges.

Case LXI.—Mrs. C. of Amsterdam, N. Y., wife of the patient whose history has just been given. There was no family history of tuberculosis, but she undoubtedly acquired the disease from her husband. It may be remarked here that Mr. C. was exceedingly careless about expectorating about him wherever he happened to be. This was so noticeable and he was so persistent in the neglect of my admonitions so frequently given, that I once forbade his coming to my office. This caused him to heed my advice while in my office, but he continued to disregard all precautions elsewhere. Mrs. C. also had numerous small cavities. The treatment was given for about two months, but without any evidence of improvement. She died a few weeks after her husband.

Case LXII.—E. B., aged twenty-eight, of Saginaw, Mich., was examined August 14, 1895. The family history has already been given. One sister died, while tuberculous, in child-birth, and another sister was under treatment (Mrs. E., Case LXIV). This man had always considered himself especially healthy and robust. About six weeks before coming to me, he began coughing and spitting up blood. He had had three slight hemorrhages in that time, and had lost twelve pounds in weight. The only abnormality that could be detected consisted of a prolonged expiratory movement over the left apex and subclavicular area. The sputum contained numerous bacilli. He remained with me only three weeks and went home with the intention of having the treatment continued. October 23, 1895, he wrote me that he had gained eight pounds. He sent me some of the sputum at that time, and there were bacilli in it. November, 1896, he reports to me that he is quite well, weighing more than he ever did before, but I have not seen him.

Case LXIII.—Mrs. H., aged thirty-eight, of Toledo, Ohio, came for treatment August 18, 1895. She had been coughing and expectorating for two years, and had spent one winter at Colorado Springs. The expectoration was free, but contained very few bacilli. There was only bronchial breathing over the upper half of the left lung and over the right apex. She remained under treatment for two months, during the latter half of which she coughed and expectorated much less and no bacilli could be found, although frequent and careful examinations were made. I last examined the sputum in December, 1895, and at that time could find no bacilli.

Case LXIV.—Miss P., aged eighteen, of Grass Lake, Mich., had been seen by me in consultation early in July, 1895. She was in the last stages of the disease, very much emaciated, and with extensive cavities. There was no family history of the disease, except that a cousin had it, and this cousin had visited at her father's house. The treatment in this case was without effect, and the patient died in November, 1895.

Case LXV.—Miss M. S., aged twenty-one, of Ann Arbor, in the last stage of the disease had the treatment for three weeks without effect.

Case LXVI.—Miss E. S., aged twenty-nine, of Ann Arbor, came for examination August 29, 1895. There was no family history and no known direct contagion. The apex and subclavicular area of the left side showed crepitant râles. The sputum was small in amount but contained numerous bacilli. Miss S. is a farmer's daughter and lives about five miles from my office. She drove this distance every day, rain or shine, cold or hot, from the time of beginning the treatment until March 1, 1896. I attribute much of the good results secured in this case to that drive. The germs disappeared in December, 1895, and she has not coughed any since early in January, 1896. Physical examination fails to show any abnormality. The temperature never went above 100° F. and has been normal since December, 1895. I believe in the curative value of out-door life. This adjunct to treatment is especially applicable to those cases in which there is but little elevation of temperature.

Case LXVII.—Mr. W., aged twenty-eight, a paperhanger, of Ann Arbor, came for examination the last of August, 1895. There was no history of the disease in his family, and no evidence of direct contagion. He came on account of a hemorrhage, having supposed himself well except that he had lost about fifteen pounds in weight during the preceding year. The bloody sputum contained numerous tubercle bacilli. The left lung showed in its upper portion moist râles. The afternoon temperature was 100° F. After four weeks of treatment the râles disappeared and there has been no cough since. He took the injections daily for nearly six months. He now weighs more than he ever did before, and has not lost more than one month from his work during the whole time.

Case LXVIII.—Mrs. W., aged twenty-eight, of Grand Rapids, Mich., was examined early in September, 1895. There was no history of the disease in her family, and none of direct contagion. There was bronchial breathing over both upper lobes. Treatment was given for six weeks, during which time the patient gained a few pounds in weight and the night sweats, which had been profuse, ceased. She then went to Colorado, and I have known nothing of her since.

Case LXIX.—Miss R., of Goshen, Ind., was examined late in September, 1895. She had numerous small cavities, profuse night sweats, and high afternoon temperature. The treatment did not retard the progress of the disease.

Case LXX.—Mr. J., aged twenty-seven, an instructor in the University, came under treatment early in October, 1895. There was no history of the disease in his family. He had worked in the same room with a consumptive two years before. There was bronchial breathing over the upper half of both lungs. The afternoon temperature averaged 100° F. The treatment was continued until the middle of February, 1896, at which time he went west for permanent residence. There was some improvement during the treatment, as shown by gain in weight and decrease in temperature. However, the bacilli remained in the sputum and the physical signs were not materially altered. November, 1896. He has steadily declined in health since going to Colorado.

Case LXXI.—Miss S., aged eighteen, of Bay City, Mich., October 13, 1895. There are certain points in this case which justify some detail. Miss S. had studied very continuously in the Bay City High School, the very moderate means of her parents having rendered it necessary that her studies should be pursued under certain disadvantages. During the last year of her high school course she lost flesh and suffered from a sensation of general weariness from which she constantly strove to relieve herself by working all the harder, and the stimulation of work actually gave her temporary relief. In October, 1895, she entered the University and soon thereafter consulted me concerning the feeling of lassitude. Nothing had called her attention to her lungs. She had observed that she felt a shortness of breath, even when walking at an ordinary gait, and much more plainly on ascending stairs, but she had supposed that this was due to a weak heart.

There was bronchial breathing over both upper lobes and both apices were retracted. There had never been any cough. The extent of lung involvement was certainly unusually great considering the entire absence of cough. The physical examination left no possible doubt in my mind as to the nature of the trouble and subsequent developments confirmed the testimony of the physical signs. The patient was put on creosote, and the administration of nuclein was not begun until later. In November, she had a slight hemorrhage and the blood raised at the time was carefully examined, but with negative results. The cough accompanying the hemorrhage soon ceased. I had requested the patient to keep a wide-mouthed bottle in her room and to bring me anything and everything she should cough up. Several times she brought me samples of saliva and mucus from the throat and nares. Early in January, 1896, I found the bacilli for the first time; then the nuclein was given. However, the lungs rapidly broke down. She was carried to Colorado in February and died there about three weeks later. This case illustrates in an unusual manner how extensively the lungs may be involved in tubercular processes before the bacillus appears in the sputum, and indeed before there is any sputum.

Case LXXII.—Mr. M., of Grass Lake, Mich., principal of the high school, was examined November 21, 1895. He had considered himself well until about three weeks before this examination, when he began to cough and raise. There was no physical sign except prolonged expiration accompanied by feeble moist râles over the left apex and subjacent area. The sputum was small in amount, but contained numerous bacilli. He remained under treatment for about four weeks, when on having an opportunity to accept a position in New Mexico, he went there. He improved slightly in weight during the treatment. There was no family history of tuberculosis; but he and his wife had during the summer of 1895 occupied the house of Mr. P., father of Case LXIII. Of course he might have been infected much earlier than this. However, I think this coincidence of sufficient importance to be recorded.

Case LXXIII.—C. M., aged twenty-five, of Pinkonning, Mich., a fireman on a locomotive. There was no family history of tuberculosis and no known direct exposure to contagion. In December, 1893, he fell on a switch-stand, bruising the abdomen and injuring one testicle, which has gradually decreased in size until it is not more than one-third as large as the other one. The injury to the abdomen caused a dull pain, which continued for some months. This pain grew so severe in February, 1894, that he summoned a physician and was in bed for one week. The physician said that he had inflammation of the bowels. Some six months later he began to cough. He had been under the charge of a physician for three months before coming to me. He had suffered during this time from a persistent diarrhea. Had profuse night-sweats, and was raising abundantly. It seemed to me that the disease had extended from the abdominal cavity upward. Both lower lobes were involved and there was a pleuritic effusion on the left lung. The afternoon temperature went as high as 103° F. This man had the nuclein injections for three weeks, during which time there was some improvement in the diarrhea, but none in the lungs. He was anxious to go west, the railroad company offered him transportation, and as I did not believe that his condition would be materially benefited by the nuclein treatment, I consented. He went to Arizona and I have heard nothing further from him. I should be much surprised if the change in climate has done him good.

Case LXXIV.—C. T., aged twenty-three, a student from Lansing, Mich. His father's half-brother had died of consumption eight months before, after a long illness in his father's house. T. had always been frail. He began to cough and raise some one year ago. Since October 1, 1895, the amount of sputum had greatly increased. His hands and feet grow cold every afternoon. There was roughened breathing over the whole of left upper lobe and some dulness over the right side. The first examination failed to reveal any bacilli, but subsequently a few were found. The injections were given for four weeks, when the cough ceased, the fever disappeared, and six pounds in weight was gained. The only evidence of any trouble in the lungs on his discontinuance of the treatment was a prolonged expiratory murmur on the left side. November, 1896, he writes that he is perfectly well.

Case LXXV.—Mrs. C., aged twenty-nine, of Seattle, Wash. There was no family history of the disease and no known exposure. She had left Seattle in September, 1895, and gone to her father's at Towanda, Pa., where she had been under the treatment of Dr. C. M. Pratt, who wrote me as follows: "Mrs. C. has been under my care for the past month for symptoms of incipient phthisis, cough, rapid pulse, night-sweats, delayed menstruation, etc. She is now somewhat better, weight increased, cough less, night-sweats better, and she has menstruated. Her treatment has been creosote, phosphate of iron, and one-sixtieth of a grain of picrotoxin for night-sweats." I found bronchial breathing over the upper part of the left lung. The quantity of sputum was small and bacilli few. Her weight was 116 pounds. She had the nuclein injections for nearly three months, before which time her cough had ceased altogether and no abnormality could be detected in the lungs. Under date of August 16, 1896, she wrote me from Sidney, Wash., that she weighed 133 pounds and had never felt so strong and well. She has not been troubled with colds and has no cough.

Case LXXVI.—Mr. H., aged twenty-four, of Decatur, Ill., came to me in August, 1895. It will be seen that this case is reported out of chronological order. This is done because it was not a case of pulmonary tuberculosis. The disease was located in the bladder. He had been troubled about three months before consulting me with frequent and painful micturition. He had been sounded for stone with negative results. Examination of the bloody urine showed the presence of numerous pin-head lumps, which, on being crushed between cover glasses and stained, revealed great numbers of tubercle bacilli. Guinea-pigs inoculated with the urinary sediment developed tuberculosis. The treatment was begun by me and continued by Dr. Barnes of Decatur. Early in September, 1895, he began his work as teacher in the Decatur High School. At that time his afternoon temperature frequently rose as high as 103° F. Before December, 1895, the urine had become normal, and had so remained. There is now no evidence of the existence of any disease.

Summary.—The cases reported in this and the preceding paper include all those in which the tubercle bacillus was found, treated by me with yeast nucleinic acid, from May, 1893, to December, 1895. There has been no selection of cases to report, and no exclusion. Many were in the last stages of the disease when the treatment was begun. Indeed, some of them were at that time confined to their rooms, and died within a few weeks. In my study of the value of yeast nucleinic acid in the treatment of tuberculosis, I have endeavored to carry out the investigation as I would a series of laboratory experiments and, above all, not to deceive myself. Of the seventy-six cases reported, seventy are those of pulmonary tuberculosis. Of these, thirty ($42\frac{6}{7}$ per cent.) have died. Of these, at least nine were temporarily benefited.

Of the seventy, seventeen ($24\frac{2}{7}$ per cent.) have been continuously free from the bacillus for from one month to two and one-half years, so far as can be determined from the sputum; *i.e.*, either there has been during this time no sputum to examine or that examined has failed to reveal the bacillus. To the best of my knowledge, another (No. 47) has been free from the bacillus for more than a year, and another (No. 29) has been free from the bacillus with the exception of a short time, and still another (No. 24) was free when last examined. Twenty ($28\frac{4}{7}$ per cent.) were still infected at the last examination. Of these, sixteen have been apparently improved by the treatment. It should be stated that none of these were hospital cases. I was not able to control their diet. Most of them were not rich, and had only inexpensive food. The hygienic conditions under which many of them have lived have not been satisfactory.

Of the five cases of urinary tuberculosis, four have apparently been cured. One was temporarily benefited, but developed acute miliary tuberculosis and died. The one case of joint tuberculosis has been benefited.

Since the first of January, 1896, I have treated between thirty and forty additional cases of pulmonary tuberculosis with nuclein, but since most of these have been given the five and the ten-per-cent. solutions of nucleinic acid by the mouth, some with and some without hypodermic injections of the one-per-cent. solution, and since sufficient time has not elapsed to draw positive conclusions concerning the value of this method of administration, I will defer further details until another time. Moreover, to report additional cases would require that this paper be lengthened beyond all proper limits.

I have treated several cases which I believed to be tuberculous, but the bacilli could not be found. These are not included in the list already given, and I will now proceed to detail two which seem to me of special interest:

In May, 1895, I was called to Battle Creek, Mich., where I saw, in consultation with Dr. Alvord, a Mr. D. His mother's family had furnished several consumptives, and a brother had had one leg amputated by Dr. John B. Hamilton of Chicago on account of tuberculosis of the knee-joint. The patient, who was unmarried and twenty-eight years old, had been failing in health for the past six months, latterly very rapidly. February 1, 1895, he weighed 136 pounds; at the time of my visit eighty-two pounds. He had an exhaustive mucus diarrhea, with night-sweats, and the temperature curve of tuberculosis. The lungs were normal and the heart very weak, but without organic disease. The abdomen was retracted, and no enlarged glands could be found. A few weeks before my visit Dr. Alvord had operated upon him for fistula in ano. The wound was still discharging. I examined the stools and the pus from the wound for tubercle bacilli, but with a negative result. I advised that the bowels be irrigated two or three times a day with large volumes of water, and that after each irrigation two drams of the one-per-cent. solution of yeast nucleinic acid with fifteen drops of laudanum be injected. Teaspoonful doses of the nucleinic-acid solution were also given by the mouth three times a day. From the time of my visit until September 1, 1895, about one gallon of the nuclein solution was used, and the patient gradually improved. By September, 1895, he was able to walk out, and in January, 1896, he resumed his work. He has continued well. His present (November, 1896,) weight is 130 pounds. He eats without discrimination, has daily normal movements, and attends to his duties as proprietor of a dry-goods house.

Miss S., of Port Huron, Mich., aged eighteen, came to me by the advice of Dr. Wilson of that place, April 4, 1895. Father and mother are both living and well. In short, the only consumptive in the family is a cousin, with whom the young lady has occasionally visited. Her weight had fallen from 129 pounds to 105 pounds within six weeks. Night-sweats were profuse and exhausting. The following letter from Dr. Wilson forms the best statement of the history of the case:

> Port Huron, April 9, 1895.
>
> Dear Doctor:—I had intended to send with the patient a statement of the origin and progress of the lung involvement, but I misunderstood the time fixed for the departure and was too late.
>
> I think it was February 18th, that her mother brought Miss S. to me. She was very anemic, weak, and feverish. I made no examination of the lungs at that time, but did four days later. I was again struck with the great anemia. The exertion of walking across the room would cause very rapid pulse and breathlessness. I found the upper part of the left lung involved. About two weeks after this, Dr. Stewart, on my invitation, examined the lung, and found a small area of dulness about the line of junction of the upper and middle lobes of the right lung. On examination I confirmed this discovery. The dulness spread up and down and in all directions from this focus, and within two weeks involved the whole of the right lung. I watched its progress closely, and know this to be a fact. The afternoon temperature soon reached 100° F., then ran up to 102°, to 103°, and sometimes to 104° F. At times I doubted my diagnosis of tubercular infection, as the cause of the dulness, but could find no other solution for it. At the time she left, the dulness was not quite so marked in the right apex as it had been. There was very little cough, for the amount of lung involved, and she had certainly gained in strength, but had lost in weight. Her appetite had also improved, and there was a morning remission in the fever, which before had been continuous. I had the nuclein and thought of using it, but concluded that it promised nothing in a case of such acute nature, so I prescribed tonics and remedies

to meet symptoms as far as possible, I will be glad to hear from you concerning her. Yours,

MORTIMER WILSON.

Menstruation had not appeared for three months past. The mother told me at the time of examination that the patient had been failing in health noticeably since early in December, 1894. My notes taken at the examination read: "Upper lobe of right lung partially consolidated and numerous râles heard throughout upper lobe of left lung. There is a distressing cough, but the patient has never raised anything." The temperature the day before beginning the treatment was as follows: 8 A.M., 98.5°; 1 P.M., 101°; 4 P.M., 103°; 8 P.M., 102$\frac{3}{5}$° F.

The treatment was begun April 5th with 40 minims, which was doubled the next day, and kept at 80 minims during the course of the treatment. The temperature gradually fell as is shown by the following: May 8, 8 A.M., 98.5°; 12 M., 100$\frac{4}{5}$°; 4 P.M., 101$\frac{4}{5}$°; 8 P.M., 100$\frac{3}{5}$° F. By the middle of June the temperature remained normal, and there has been no fever since that time. When I state that the temperature gradually declined I would not have it understood that there were no exceptional days. In the latter part of April the temperature for some days ran high at 4 P.M., and once reached 104° F. The treatment was discontinued the last of June, and there has been no occasion to resume it since. At that time the lungs were quite normal and the cough and night-sweats had ceased. In October, 1895, Miss S. wrote me that she weighed 130 pounds and was quite well. In March, 1896, I saw her and she was apparently in the best of health. I did not examine her lungs.

I have reached certain positive and definite conclusions concerning the value of the one-per-cent. solution of yeast nucleinic acid in tuberculosis administered daily in doses of from 60 to 80 minims hypodermically, and these conclusions I will now give:

1. In advanced stages of the disease, in which the area of involvement is great, with or without cavities, the best that can be expected from this treatment is temporary improvement. Even this does not occur in all cases.

2. In inital cases, when the area of infection is limited, this treatment may and often does, not only arrest the progress of the disease, but it acts as a curative agent.

If these conclusions be correct, it follows that in order to save our tuberculous patients by the employment of this treatment, we must recognize the disease in its incipiency. How can we best do this? That the presence of the bacillus tuberculosis in the sputum is a positive and conclusive proof of the existence of pulmonary tuberculosis, I assume that no one will deny. If the sputum were examined for the bacillus in every case in which there is any sputum, and as soon as there is any, thousands of cases of tuberculosis would be recognized in time for therapeutic measures to be effective. I employ the word "sputum" here as I think it is generally understood by the profession, and not as it is defined in our medical dictionaries, nor do I use it in strict accord with its etymology. I mean to designate by the word "sputum" any secretion which has its origin in the air passages below the epiglottis, and which is ejected from the mouth. It will be seen that according to this definition saliva is not sputum, though the latter may be mixed with the former. With this definition, I say that in any instance in which the patient raises any sputum, an examination for tubercle bacilli should be made. Neither the robust appearance of the patient nor his previous excellent health, nor his family history, possibly free from any taint of tuberculosis, should cause the physician to neglect this examination. As a profession, we have been so long, so forcibly, and so painfully impressed with the old, classical picture of this disease, when it was known only in its last stages, that even now we too often fail to recognize it in the distance from failure to employ the aids to our vision with which science has recently equipped us. It is my belief that, so far as tuberculosis is concerned, our profession is to-day in greater need of skill among its members in the early recognition of the disease than it is of therapeutical agents with which to combat it.

While the careful examination of the sputum would be of great service in the early recognition of tuberculosis, I believe that in many cases the diagnosis of this disease may be and should be made before there is any sputum to examine. I will illustrate this point by the history of the following case, which I have just examined, and which might be duplicated almost any day in the practice of one giving special attention to this disease:

Miss G., aged twenty-six, a saleswoman in a dry-goods store. Her mother died, twenty years ago, of consumption. One sister died twelve years ago of the same disease. The family has lived during all this time in the same house. During the summer of 1894, Miss G. weighed 130 pounds, and was apparently a robust, vigorous woman. In August, 1895, she weighed 118 pounds, and consulted a physician for the first time in her life. She complained of great and constant weariness, loss of appetite and chilly sensations, followed by slight fever, every afternoon. The physician to whom she went in August, 1895, has treated her from that time until now for malaria and "liver trouble." In March, 1896, she had the *grippe*, and began to cough, for the first time in her life. She has been coughing ever since. Now she weighs 104 pounds, has profuse night-sweats, coughs almost constantly, and there is not a normal respiratory sound to be heard in any portion of her lungs.

Now, I wish to ask, When should the treatment for tuberculosis have been begun in this case? Did the *grippe* of March, 1896, develop the tuberculosis? What caused the loss in flesh so plainly recognized in August, 1895? What caused the daily chilly sensations and the afternoon fever at that time? Are not the chances ten to one—yes, one hundred to one—that she was tuberculous then? Are we to wait until the bacillus grows vigorously and lung tissue begins to break down before we even suspect the existence of a disease so frequently present that it destroys one-seventh of the race? Does the surgeon wait until the inflammed appendix ruptures and every doubt of the nature of the trouble is removed by the collapse of the patient before he operates? If he did this, would the operation statistics for appendicitis be as favorable as they now are? I have no doubt that a healthy appendix is sometimes found by the operator, and it might happen, did we not wait for the appearance of the bacillus, that some non-tuberculous person would be treated for that disease, but the operation, skilfully done, does not kill, nor would the treatment for tuberculosis do harm. In many cases tuberculosis can be recognized before the bacillus appears in the sputum, with as much certainty as appendicitis can be diagnosed before rupture occurs.

Have we not a well-known method for the recognition of malaria when it has a real existence? Have we not in quinin, the one specific known to scientific medicine, a test for malaria? We have these, but we do not take the trouble to examine a drop of blood from the finger for the plasmodium, and although quinin fails to prevent the daily return of the afternoon "flush," we excuse our neglect, console our patients, and give the bacillus tuberculosis ample time to destroy the lungs, while we fire our quinin pills and capsules at a phantom.[1]

The physician who desires to recognize tuberculosis in its earliest stages must take into consideration all the known signs and symptoms of the disease. In one instance the bacillus may appear in the sputum early, in another late, and in a third not at all. In our reliance on the detection of the bacillus, we must not neglect the evidence which we may gain by auscultation, by percussion, by carefully watching the temperature, etc. I will put in condensed form my ideas concerning the means which should be employed in the early recognition of tuberculosis:

1. Whenever there is any sputum it should be examined for tubercle bacilli. If the bacilli are not found in the first examination the search for them is to be repeated. When the bacilli are present the diagnosis of tuberculosis is positive. Failures to find bacilli, even after repeated examinations, does not prove the absence of tuberculosis. The complete absence of cough and of sputum is not proof of the non-existence of tuberculosis.

2. Apical catarrh, even when no bacilli are found in the sputum, is in the great majority of instances due to tuberculosis. Leube is certainly right when he says: "Marked dulness of the percussion note over the apex is always ('fast immer') a symptom of pulmonary tuberculosis, especially when the dulness is unilateral, and is detectable also in the infra-clavicular fossa or in the regio supraspinata. . . . Still more certain is the diagnosis when the dulness on percussion is accompanied by auscultatory variations from the normal. The slightest variations in the respiratory sounds suffice here, such as jerky breathing, prolonged expiration, feeble or intensified, or rough vesicular breathing, and indefinite respiratory sounds. If the breathing be of bronchial character, or if there be râles, even when these are isolated, the slightest percussion dulness in the apex becomes of great diagnostic significance."

Among the very earliest variations in respiratory sounds in tuberculosis is a prolonged expiratory movement. When this is accompanied by retraction of the apex and dulness on percussion, there can be but little doubt about the diagnosis. This prolongation of the expiratory sounds is so easily and so certainly recognized and its diagnostic value is so great that I wish to emphasize this mention of it.

There is a tendency among medical men at present to pronounce no disease of the lung tuberculous unless the bacillus is found in the sputum. I had myself fallen for awhile into this error. Such cases as the following lead me to believe that this is an error:

P., now aged fifty-six, had consulted me occasionally for years. As early as 1893 he began to lose weight and to complain of weariness upon slight exertion. This decrease in weight has slowly continued. During the winter of 1894–95, he had frequent and persistent colds, during which he coughed up mucus. There was at that time only a prolonged expiratory sound over the right apex and subclavicular region. The sputum was examined during these colds, but always with negative results. In the fall of 1895, he returned from his vacation with a well marked apical catarrh on the right side. The sputum was examined repeatedly during the following winter, but again negatively. On account of the failure to find the bacilli, the nuclein was not employed. In September, 1896, he returned from a three-months' vacation with a cavity under the clavicle on the right side, with the left upper lobe involved and his sputum laden with bacilli.

---

[1] It is an interesting fact that malaria was once regarded as antagonistic to tuberculosis. This view was especially championed by Buffalini and other Italians, and this supposed antagonism was cleverly used hy Brehmer in explaining his theories. See "Die Gesetze und die Heilbarkeit der Chronischen Tuberculose der Lunge," Berlin, 1856.

3. I will again quote from Leube as follows: "It has recently become more and more certain that the apparently spontaneous pulmonary hemorrhages which occur in those supposedly well are not causes of tuberculosis, but are the results of a disease already established." The teaching of Niemeyer[1] that pulmonary hemorrhage is a cause of tuberculosis was founded upon erroneous ideas of both the etiology and pathology of the disease and should have been discarded years ago. I have already called attention to the desirability of examining the blood for tubercle bacilli in every case of pulmonary hemorrhage. The germs will not always be found, even when the hemorrhage is of tubercular origin, as it is in the great majority of instances, but when they are found there can be no longer any doubt about the nature of the lesion. I have seen so many cases in which the golden opportunity for beginning proper treatment, medicinal or climatic, has been indicated by hemorrhage, the warning has been disregarded, and the disease has next manifested itself in a grave form, that I desire to briefly report one such case:

A young lady of eighteen had in February, 1895, a slight hemorrhage and continued for some days to cough up blood. A physician pronounced it vicarious menstruation, finding some reason for this in the fact that the monthly flow had been somewhat scanty. The young lady began to cough late in the spring of 1896, and an examination of the lungs in July of this year showed dulness over both upper lobes, bronchial breathing with bubbling râles, a small cavity in the left subclavicular area, and an extensive pleuritic effusion over the lower half of the right lung. The sputum contained innumerable pinhead tubercles, and these crushed between cover glasses and stained were found to be full of bacilli.

Now, can any one with the subsequent history known doubt that this patient was tuberculous in February, 1895? With instances of this kind coming under professional observation constantly it does seem that we should interpret the significance of early hemorrhage more correctly.

The studies of Rindfleisch have made us acquainted with the pathology of hemorrhage in initial tuberculosis. The tubercular process extends into the wall of the artery destroying the media and at times the intima, thus forming a spot where the rupture occurs. Fortunately this usually happens in one of the very small end arteries, and the hemorrhage is consequently slight. According to Rühle, late hemorrhages are of somewhat different origin and are more likely to be serious. Here the arteries in the walls of cavities, being left unsupported by the destruction of the adjacent tissue form aneurismal sacs which break.

There is considerable difference of opinion among the authorities concerning the effects of hemorrhages in pulmonary tuberculosis upon the temperature. According to Wunderlich,[1] Lebert,[2] and Schwarz,[3] even slight hemorrhages in any and all stages of the disease are followed by at least a temporary depression of temperature. While Niemeyer[4] and Uhrig[5] state that hemoptosis is usually followed by an elevation of temperature, and Simonsohn,[6] that there is no uniformity in the effects, I wish to state in this connection that when a supposedly healthy person has come to me on account of pulmonary hemorrhage I have always found at some time of the day, usually in the afternoon, an elevation of temperature. Of course I cannot say whether these persons were febrile before the hemorrhage or not.

4. It is stated by good authorities that some cases of pulmonary tuberculosis run their entire course without any elevation of temperature. I have never seen such a case. I fail to find any such case reported in sufficient detail to justify me in believing the statement to be true. When the temperature is taken only morning and evening, the record may show no elevation; especially is this likely to be true when the evening record is made late. However, this is not the correct method of taking the temperature in this disease. The maximum temperature is, in the great majority of instances, in the afternoon, and not in the evening. My experience leads me to believe that the temperature curve of tuberculosis is as characteristic as that of typhoid fever; and, indeed, there are fewer variations than in typhoid. While there are exceptions and while exercise often markedly alters the temperature of a given hour, the rule holds that the maximum is between three and six P.M. The record should always be made at eight A.M., twelve M., four P.M., and eight P.M. When this is done the maximum will, in the majority of instances, when averaged for a week, be at four P.M.

In acute miliary tuberculosis the temperature curve is very irregular and my observation confirms the statement of Rühle[7] who says: "The irregularity of the fever curve of miliary tuberculosis is of importance in distinguishing it from other febrile diseases from which it otherwise might be confounded."

It would seem to be superfluous to say that but little reliance can be placed on the patient's statement that there is no fever. However, I have this day received a letter in which a physician writes substantially as follows: "Mrs. A. has been tuberculous for two years. She states that she has been free from fever, but I find that since I began the nuclein her afternoon temperature sometimes goes as high as 101° F." In all cases it is well to have a temperature record for a week before treatment is begun.

[7] "Die Lungenschwindsucht und die Acute Miliartuberkulose." Ziemssen's *Handbuch*.

Burkhardt, working under Strumpell, has written a monograph on the temperature in tuberculosis.[1] This monograph is a good illustration of the careless mannner in which the temperature in tuberculosis has been studied even in some of the most renowned clinics. Burkhardt makes five classes of temperature curves in tuberculosis:

(1) Afebrile, both in the beginning and during the course of the disease. (2) Subfebrile: "In a large number of cases the morning temperature is (zwar) normal, while the evening temperature shows a slight elevation (from 38° to 38.5° C.)." (3) Hectic fever: "The morning temperature is normal, while the evening temperature goes to 39° or 39.5° C." (4) Continued fever (Volliges Verschwinden normaler Eigenwärme). (5) Irregular temperature (Grosse Unregelmässigkeit des Wärmeganges).

5. Loss of weight is practically a constant and frequently an early accompaniment of tuberculosis. However, before any significance can be attached to loss of weight in our endeavor to make an early diagnosis, other causes of the loss must be excluded. Loss of weight, when coupled with the characteristic temperature curve furnishes very strong presumptive evidence of the existence of tuberculosis in some part of the body. Much has been said about a "pretubercular" condition, in which there is a decrease of weight, a sensation of general weariness, and loss of appetite, and which is supposed to render the person especially susceptible to tuberculosis. It is in these cases that an attack of influenza, measles, whooping-cough, pleurisy, pneumonia, or a "bad cold" is so frequently supposed to be the starting point of consumption. The physician recognizes this so-called "pretubercular" condition. Sometimes he administers iron, quinin, and other tonics, and thus tries to prepare the patient for the disease to which he is supposed to be specially susceptible, and I am by no means ready to deny that this treatment is beneficial. However, the mistake is made in looking upon this condition as "pretubercular;" it is tubercular, and the time to treat it is before the tuberculosis becomes a mixed infection by the advent of some intercurrent disease.

In taking the weight it is well to use the tables of Quetélet[1] or some modification of the same as a basis of comparison. Conradi[2] has given us a valuable paper on the decrease in body weight in tuberculosis, and he has pointed out the fact that decrease in weight is important evidence of the disease in its early stages. This decrease is due to want of assimilation; later, it may be in part due to fever. Conradi has pointed out the following facts: (1) The decrease in weight is greater in proportion to the prostration accompanying it than in most diseases. (2) The younger the patient the greater will be the loss in weight necessary to induce prostration. (By prostration the author here means inability, from weakness of the patient, to attend to his ordinary duties.) (3) After prostration decrease in weight continues, but, as a rule, not so rapidly.

Besides the above-mentioned evidences of tuberculosis there are many other conditions which should lead us to suspect the existence of this disease. Although thirty years have passed since Flemming[3] showed that pleurisy is due in a large per cent. of the cases to coexisting and preexisting tuberculosis, the profession has given but little attention to this matter, and attack after attack of pleurisy in the same individual is treated, while the tuberculosis, which is the cause of the pleurisy, is never thought of until the lungs are practically destroyed.

In 106 *post-mortems* Schlenker[4] found the pleura normal in twenty-one bodies (19.8 per cent.); pleura diseased in eighty-five (80.2 per cent.). The pleurisy was associated with extensive tubercular changes in the lungs in twenty-eight (26.4 per cent.); with latent tuberculosis of the lungs or bronchial glands in thirty-three (31.1 per cent.). There was tuberculosis without pleurisy in four (3.4 per cent.); and pleurisy without tuberculosis in twenty-four (22.6 per cent.). The author states that if tubercular lesions had been sought for microscopically the number of cases of pleurisy without tuberculosis would have been decreased.

I have come to believe that when physicians acquire and practise in the diagnosis of tuberculosis a degree of skill equal to that employed by surgeons in the recognition of appendicitis, pulmonary tuberculosis will be detected in its earliest stages; and when this is done it will be placed among the most easily curable of the graver infectious diseases.

CLINICAL MEMORANDA.

A CASE OF SPLENO-MEDULLARY LEUKEMIA; ONE OF LYMPHATIC LEUKEMIA, OR SPLENIC ANEMIA; AND FOUR CASES OF PERNICIOUS ANEMIA.[1]

BY H. A HARE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE JEFFERSON MEDICAL COLLEGE; PHYSICIAN TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL.

THE cases that I desire to show you to-night are three in number; and, in addition, I shall speak of three others. Of these six cases, representing various types of blood disorder, one is a case of undoubted spleno-medullary leukemia, and the diagnosis of the second lies between splenic anemia and lymphatic leukemia. The other four are cases of pernicious anemia.

The first case is that of D. B., aged thirty-three years, of Wilmington, Del., who is single and by trade a carpenter. He came under treatment October 7, 1896. His family history is negative. Two brothers and three sisters are in good health. The patient has worked in the Wilmington Car Shops for about sixteen years, and has never been seriously ill. He has never had chills, fever, or sweats, but has lived in a malarial district. He has been in the habit of drinking two or three glasses of whisky a day, and has occasionally gotten drunk. There is no specific history. Five years ago he began to have indigestion, the result, as is supposed, of irregular and hasty eating. These attacks consisted of headache and vomiting, were often accompanied by fever, and occurred at irregular intervals until the present trouble began. Five months ago he noticed a fulness of the abdomen, which he thinks has not increased in size since then. He did not suffer pain, but had a heavy dragging sensation in the stomach. He paid but little attention to his trouble and kept on working. About three months before admission he was conscious of a gradually increasing weakness, and this being accompanied by considerable dyspnea, he decided to consult his family physician, Dr. Brown of Wilmington, who treated him for several weeks and then brought him to the Jefferson Medical College Hospital.

On the day of his admission an examination of his abdomen revealed an immensely enlarged spleen extending considerably beyond the median line and to about three inches below the umbilicus. His general condition was good, and he had kept at work up to the date of his admission. His tongue was only slightly coated, the bowels were regular, and the appetite fair. His urine was acid in reaction, the specific gravity was 1024, and it did not contain albumin or sugar. Microscopic examination was negative. An ophthalmological report made on October 16th revealed the fact that the media and fundus were normal, that the field for form and color was normal, and that the veins were large and tortuous. There was no evidence of hemorrhage.

The patient was given increasing doses of Fowler's solution of arsenic until, at the end of a month, he was taking eight drops three times a day. He also received a dram of fluid extract of ergot thrice daily. On November 16th, on account of gastric irritability, fifteen drops of the Fowler's solution were given daily by the rectum, the ergot being continued by the mouth. The arsenic solution was gradually increased until forty-one drops were given twice daily, still per rectum. On December 7th the solution was increased to forty-five drops a day, in three doses, but on December 20th it was stopped on account of diarrhea. On the 21st he was given fifteen drops of the arsenic solution and a dram of ergot by the mouth daily, and this was continued until January 12th, when I went on duty at the hospital. The administration of the ergot was then stopped, but the Fowler's solution was continued, and was increased until he was taking thirty-two drops daily. On the 20th gastric disturbance again developed, and the arsenic was discontinued, but on February 2d it was resumed, but in smaller amounts. The examinations of the blood, from the date of his admission to the present time, have given the following interesting results:

Date.	Hemoglobin, per cent.	Erythrocytes.	Leucocytes.	Proportions.
Sept. 30, 1896	28	2,458,000	368,750	1 to 6, L. 6 per cent., M. 15 per cent., P. 60 per cent., E. 5 per cent.[1]
Oct. 2, "	25	2,700,000	386,000	1 to 7.
" 16, "	28	2,800,000	241,666	1 to 11.
" 26, "	40	2,322,000	139,000	1 to 16, L. 1 per cent., M. 28 per cent., P. 51 per cent., E. 4 per cent., My. 3 per cent.
Nov. 8, "	45	2,064,000	118,000	1 to 17.
" 20, "	50	2,148,000	93,750	1 to 23.
Dec. 25, "	60	3,600,000	217,190	1 to 17.
Jan. 9, 1897	63	4,000,000	60,000	1 to 68, L. 4 per cent., My. 4 per cent., P. 66 per cent., E. 10 per cent., M. 6 per cent.
Feb. 2, "	63	4,000,000	19,000	1 to 210.
" 16, "	70	4,100,000	80,000	

It will be seen, therefore, that at first the condition of the blood was bad, there being 368,750 white cells to 2,458,000 red ones. Myelocytes were present, and the lymphocytes were decreased in number. The number of polynuclear cells was about normal, and the number of the mononuclear cells increased.

Physical examination of the patient, January 12th, showed the spleen to be enlarged, as shown in the accompanying picture (Fig. 2). At the present time it has decreased two-thirds in size, and the man is almost well.

The second case presents a most interesting history. The patient was under my care for several months a year ago. At that time the splenic enlargement was such as is shown in Fig 3.

There were areas in which loud anemic murmurs were heard; his color was sallow, and his eyes had that peculiar fatty, yellow appearance seen in some cases of pernicious anemia. His history is as follows:

---

[1] Read before the Philadelphia County Medical Society, March 10, 1897.

[1] The letter L. stands for lymphocytes, M. for mononuclear leucocytes, P. for polynuclear or polymorphous leucocytes, and E. for easinophiles. My. stands for megalocytes.

J. P., aged twenty-four years, single, a barber by occupation. Both parents are dead, the cause of death being unknown. One brother died in infancy, and one sister, six or seven years ago, of pulmonary consumption. Two sisters are alive and well. The patient stated that he had never been in the habit of taking whisky, and has smoked only in moderation. He had measles at seven years of age, and an attack of *grippe* seven years ago that confined him to bed for four weeks. Part of this time he was delirious. In February, 1894, he states that he had a severe attack of double pneumonia, but completely recovered in five weeks. In November of the same year he, at that time being a miner, lost his balance while at work and rolled for a distance of about thirty feet, sustaining considerable injury to the head and neck. He was unconscious when picked up, but reacted speedily, and two weeks later resumed work.

FIG. 1.

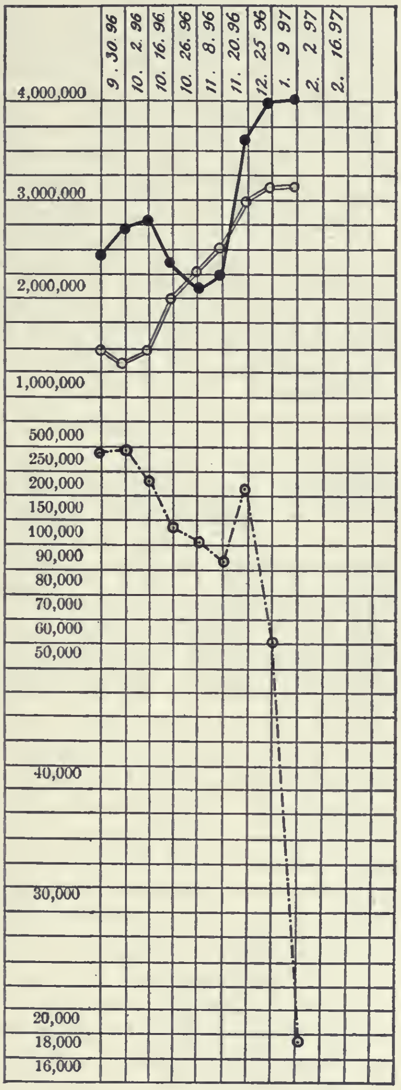

Chart showing the *great decrease in white cells* and the *increase in red cells* and in hemoglobin in Case I. of spleno-medullary leukemia.

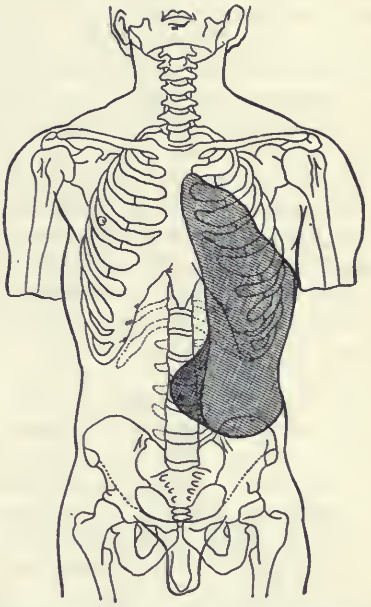
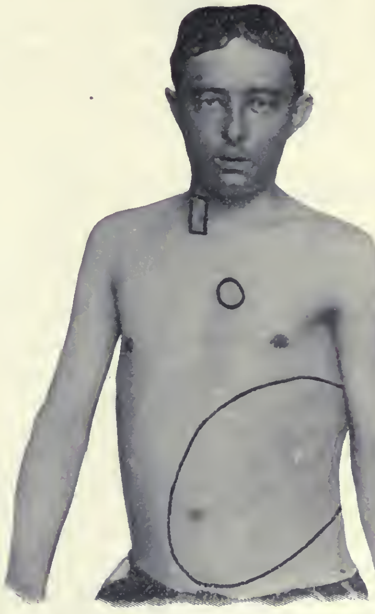
FIG. 2.



CASE I.—January 12, 1897. Lightly shaded area shows area of cardiac and splenic dulness on percussion. The dark addition near the umbilicus shows the additional splenic area discoverable on palpation. On March 10, 1897, the spleen extended only to three inches below the last rib in the mamillary line.

On October 8, 1895, he was admitted to the Jefferson College Hospital for the first time, and stated that his illness began in July, 1895, the onset being marked by moderately severe pain beneath the clavicle. It persisted at this

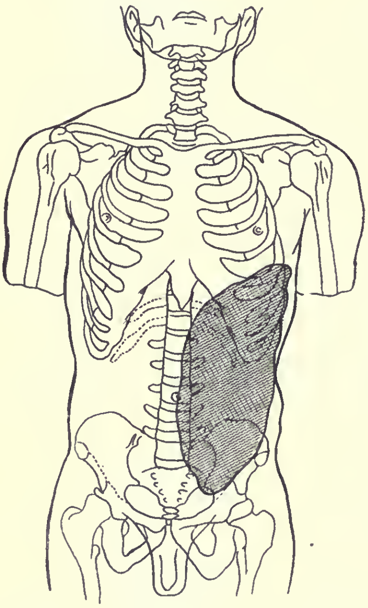
FIG. 3.



CASE II.—The large outline shows the splenic area; the smaller ones the situation of anemic murmurs.

point for three days, and then descended to the left hypochondriac region and became intense. A few days previous to the onset of pain, he noticed puffiness beneath the eyes and a decided swelling of the entire face. Profuse sweating occurred coincidently with the pain, the face became pale, and the pulse rapidly increased in frequency until it numbered 160 per minute. The respirations were embarrassed, and the temperature was 100° F. There was complete loss of appetite, and the bowels were constipated. He also states that he was unconscious for a period of three days. Loss of flesh and strength was marked, and his weight diminished from 130 to 116 pounds. He remained in bed for one month afterward and regained his weight, but the pain, varying in intensity, continued in the region of the spleen. There was a sense of weight in this region which became more and more perceptible, particularly, when the body was jarred.

FIG 4.



CASE II.—January 12, 1897. Shows area of splenic dulness as compared to the illustration showing its size in 1896.

When admitted to the hospital the most noticeable feature of the case was the extreme pallor of the face. The conjunctivæ were tinged with yellow, and the complexion was sallow. The lips, gums, and tongue were bloodless. The tongue was clean but flabby, the appetite fairly good, the bowels regular, the pulse 94, the respirations 22, and the temperature 102.4° F. Examination by palpation showed a large mass occupying the left hypochondriac region and extending back into the lumbar region. Auscultation of the heart revealed an anemic murmur at the base. A venous hum was heard in the neck.

The urine was amber colored, acid in reaction, and of a specific gravity of 1025. There was no albumin or sugar. Urea was present in the proportion of four grains to the ounce. The microscope showed red blood-cells in abundance, and a few granular leucocytes and epithelial cells.

On October 30, 1895, an ophthalmoscopic examination showed numerous hemorrhages through the retina of each eye. They were old and irregular in outline, and especially abundant near the disks. The veins were large and tortuous. On October 21st and 23d the patient had several slight attacks of epistaxis. He left the hospital on December 23d, promising to return to the out-patient medical department to have his blood counts made. On February 4, 1896, he returned complaining of hematuria. He was slightly paler, but was in about the same condition as when he left the hospital. He now remained in the ward until July 6, 1896, when he was discharged, against the wishes of the physician in charge, but slightly improved, and went to work as a barber. He again returned to the hospital on January 9, 1897, and said that he had felt very well all summer until September, when he was put on very poor diet, consisting of tea, coffee, rye-bread, and a little meat at noon. He gradually became more and more weak until New Year's day, but still kept at work, complaining of general weakness, headache when in the erect position, shortness of breath, and swelling of the feet and limbs, especially after standing. He made the journey to the hospital in the ambulance.

On admission to the wards his temperature was 101° F.; pulse, 130, and repirations, 24. On January 13, 1897, the writer again went on duty, and examination showed murmurs to be present in the carotids. The anemic murmurs were not as marked as they were last year. He had severe bronchitis due to exposure. The degree of splenic enlargement is shown in Figure 4. On February 20th and 21st he had attacks of epistaxis. He was ordered fifteen grains of ferratin three times a day.

His blood examinations have given the following results:

Date.	Hemoglobin, per cent.	Erythrocytes.	Leucocytes.	Remarks.

The large number of lymphocytes (eighty-four per cent.) in this case would apparently place it under the head of that somewhat rare type of leukemia called lymphatic leukemia, but there is an entire absence of enlargement of the lymph glands and, what is far more important, the increase in lymphocytes is purely relative, the total number of white cells being actually lower than normal. Aside from this state of the white blood cells, the case might well be classed with what has been called pure splenic anemia, or splenic pseudo-leukemia. Thus, we find the enlarged, and at times painful, spleen, the fact that the disease is commonly found at this patient's time of life, and in his sex, and that the anemic fever has also been present. Further than this, in splenic anemia we often have a decrease in the number of red cells to one-half, with a similar falling off in hemoglobin. Banti has regarded this state as a purely splenic form of pseudoleukemia, or Hodgkin's disease.

The third case is one of true pernicious anemia, which may, perhaps, be placed among the few that have been cured. The patient certainly shows a wonderful improvement, and one that is more marked than is usually met with in cases of this disease. He is before you, and you can at a glance perceive his ruddy hue. His history is as follows:

F. R., aged thirty-nine years, a lumberman, single, born in Ireland. He was admitted to the Jefferson Medical College Hospital on May 11, 1894.

His parents died at an advanced age, the cause of death being unknown to him. They had always been very healthy. The patient is one of nine children and, so far as is known, all of his brothers and sisters have always been in good health. His previous history is that he had some of the diseases of childhood, but after that was exceptionally strong and healthy, having no sickness of any kind until about twenty years of age, when he had an attack of serous diarrhea, which lasted all summer. The cause of the attack is not known. The diarrhea disappeared during the winter, but has persisted every summer since the first attack, with occasional outbreaks, however, during the winter months. Fourteen years ago he had croupous pneumonia. He was sick three weeks, and then recovered completely. After this he had good health, excepting the above-mentioned diarrhea, until April, 1893. At that time he began to have nausea, with with occasional attacks of vomiting, unconnected with the taking of food. The vomited matter consisted usually of greenish mucus or fluid, but was never in large quantity. During the worst periods of the attacks he would vomit two or three times daily. He had a poor appetite, and noticed that his skin was quite yellow. His diarrhea and vomiting continued to get worse, and in May, 1893, he entered the Williamsport Hospital, where he remained four months, under treatment for "some disease of the liver." After leaving the hospital he felt better, the vomiting ceased, the diarrhea had disappeared, and he had gained considerably in weight, but he remained very weak. He worked for a while driving a team, but this work soon became too hard for him, and in April the old trouble returned as before, and continued to grow steadily worse. He decided to come to Philadelphia for treatment, and was admitted to Jefferson Hospital on May 11, 1894.

His condition on May 18, 1894, was as follows: He presented a markedly anemic appearance, the skin having a slightly yellowish tinge. The lips and ears were almost bloodless, and the tongue pale, but clean. His appetite was fair, and his bowels quite loose. He had been gradually losing weight. His temperature ranged from 99° to 101° F., his respirations from 24 to 30, and his pulse from 68 to 80.

An ophthalmological examination showed that his pupils responded to light and accommodation. The conjunctivæ were infiltrated with a lemon-yellow fat. There were numerous fresh and old hemorrhages into the retina. The disks were anemic, and the veins and arteries could scarcely be distinguished on account of the pallor of the blood. A chest examination showed the skin to have a light yellow tinge, with extreme pallor and superficial edema. The respiratory movement was good, and there was slightly increased vocal fremitus on the right side. Auscultation and percussion were negative. The impulse of the heart could scarcely be felt. The apex beat was normal in position, but it could only be determined by auscultation. There was no increase in cardiac dulness. Auscultation revealed a soft systolic murmur, heard best at the base and at the second costal cartilage at the left of the sternum, which was not well transmitted into the neck. The liver was normal in size and could not be palpated. There was no increase in the area of splenic dulness. The abdominal examination was otherwise negative. The feet were slightly edematous. The urinary examination showed it to be acid in reaction and light yellow in color. No albumin or sugar could be found. The specific gravity was 1014. Repeated examinations of the feces did not reveal the presence of parasites of any description. The sputum examination was negative.

The blood examination gave the following results:

Date.	Hemoglobin, per cent.	Erythrocyes.	Leucocytes.	Volume, per cent.	Remarks.
May 14, 1894	15	973,000	7000	25	Microcytes, macrocytes, poikilocytes.
June 14, "	10	664,000	5000	14	
July 9, "	50	2,500,000	5000	50	Almost all corpuscles are normal.
" 24, "	55	2,600,000	8000	52	
Aug. 14, "	55	2,650,000	9275	53	
Sept. 12, "	60	3,800,000	10,000	76	

The patient was discharged from the hospital September 13, 1894, very much improved in health. His symptoms had all disappeared. He then went to work in the pine forests of Bradford Co., Pennsylvania, and his old trouble gradually returned. He was again admitted to the hospital August 28, 1896. He was very weak and anemic, and had diarrhea and vomiting, with pain over the epigastrium. He also had considerable cough with a clear, frothy expectoration. The urine was acid in reaction, and had a specific gravity of 1022. No albumin or sugar was present. The ophthalmologic report on September 22, 1896, was as follows: Pupillary reaction normal; conjunctivæ pale; media clear; nerve white; veins tortuous; retina apparently normal in both eyes. Vision O. D. $\frac{6}{8}$; O. S. $\frac{6}{30}$. In the right eye no hemorrhages had occurred, the veins were full, and there was some chromatic disturbance. The left eye showed a round disk, very pale, full veins, and a patch of choroiditis near the nasal side of the disk. Following is the record of his blood count since his last admission:

Date.	Hemoglobin, per cent.	Erythrocytes.	Volume, per cent.	Leucocytes.

Under full doses of arsenic and sulfate of iron the number of red blood-corpuscles has increased from 886,000, on September 22d, to 4,360,000 on February 18th. He presents every aspect of being cured, although the possibility of a fatal relapse is always to be remembered in this disease.

The fourth case is also one of pernicious anemia, the patient being temporarily better, but not so markedly so. S. S. D., aged sixty-one, consulted me January 30, 1895, stating that for two months he had not been feeling well. His stomach and bowels were out of order, and his fingers and feet were cold, but he did not cough. There was no mucus in his stools, and his sleep was not disturbed. An examination of his urine gave negative results. This condition of general debility improved under treatment, and I did not see him again until the twenty-fifth of the following October, an interval of nearly nine months, when he came back complaining of slight debility. I saw him again on March 17, 1896, when he complained of gastric disturbance, for which I gave him condurango. I noticed that his face was a little drawn to the right side and that he was markedly anemic in appearance, but he stated that he had always had this chalky color and was naturally pale. Ten days later he was somewhat better, and on June 25th he reported himself as being very much improved. I did not see him again until November 12, 1896, at which time he presented himself in a condition of very advanced anemia. There was a faint mitral systolic murmur, some dyspnea on exertion, and his fingers were a little blue. His urine analysis was negative. Three weeks later he came to my office again complaining of very great shortness of breath, the dyspnea being so marked as to seriously incommode his movements. At this time an examination of his blood gave the following results: Hemoglobin, thirty per cent.; corpuscles, volume, twenty-five per cent.; number, 1,332,000; leucocytes, 5000; lymphocytes, ten per cent.; mononuclear leucocytes, thirty per cent.; polynuclear leucocytes, fifty-five per cent.; eosinophiles, five per cent. The blood also showed marked poikilocytosis, and microcytes, and macrocytes were present, the latter being very large. There were also numerous normablasts and gigantoblasts. Macroscopically, the appearance of the blood was slightly paler than normal. It was quite thin and did not coagulate readily.

He was immediataly put upon peptomanganate of iron and ascending doses of arsenic. Ten days later the dyspnea was still present, but his sleep was better. I then ordered for him a wineglassful of maltale twice a day. His blood count at this time showed: Hemoglobin, twenty-eight per cent.; red corpuscles, volume, thirty per cent.; number, 1,060,000; white cells, 8000; lymphocytes, sixteen per cent.; mononuclear cells, twenty-five per cent; polynuclear cells, fifty-nine per cent.; eosinophiles, none. The difference in the count and in the results from the hematokrit seemed to be caused by the megalocytes; otherwise, the condition of the blood was practically the same as at the previous examination in regard to poikilocytes, microcytes, and megalocytes.

On January 23d, the patient expressed himself as feeling much better, and he *looked* much better. At this time the hemoglobin was 35 per cent.; red corpuscles, volume, 33 per cent.; number, 1,520,000; white cells, 6000; lymphocytes, 16 per cent.; mononuclear cells, 32 per cent.; polynuclear cells, 52 per cent.; no eosinophiles. There were only a few poikilocytes and megalocytes. It is noted the blood showed a marked improvement over previous examinations.

On January 6th, 1897, the examination resulted as follows: Hemoglobin, 37 per cent.; red cells, volume, 42 per cent.; number, 2,212,000; leucocytes, 6300; lymphocytes, 20 per cent.; mononuclear cells, 16 per cent.; polynuclear cells, 60 per cent.; eosinophiles, 4 per cent. Microscopic examination revealed a few microcytes and macrocytes, and only an occasional poikilocyte.

On February 2, 1897, he reported that he had gained eight pounds since December 1st. The liver and spleen are still normal in size, the appetite is good, and the bowels regular. He sleeps well, does not cough, and there is much less shortness of breath. He has taken the maltale regularly, but during his entire illness has never been able to take more than six to eight drops of Fowler's solution of arsenic a day, with pepto-mangan, without developing gastric irritability. He has had massage twice a week for six weeks. An examination of his blood at this date showed: Hemoglobin, 45 per cent.; red cells, 2,400,000; volume, 46 per cent.; leucocytes, 10,000; lymphocytes, 5 per cent.; mononuclear cells, 25 per cent.; neutrophile cells, 70 per cent.; eosinophiles, 5 per cent.

Microscopic examination shows a few poikilocytes and microcytes.

On February 24, 1897, he reported that he was improving in every way. An examination of his blood gave the following results: Hemoglobin, 35 per cent.; erythrocytes, 2,250,000; leucocytes, 12,500. A few microcytes, rather numerous macrocytes, and a considerable number of poikilocytes were present. This case showed marked improvement on active hematic treatment. Whether the improvement will persist remains to be seen.

The fifth case, also one of pernicious anemia, is that of F. L., born in Pennsylvania, aged forty-four years, a carpenter by occupation. He was admitted to the Jefferson College Hospital with the following history: His father died of alcoholism. His mother had some nervous affection. His brothers and sisters are all living, and healthy, in his opinion, but cross examination showed that one sister was decidedly pale, and had white patches on the skin such as he had. The patient had the ordinary diseases of childhood, and malarial fever eleven years ago, which lasted six months. Otherwise he has always been strong and healthy until four years ago, when he began to suffer from weakness, but was not confined to bed. He has never lost flesh, does not cough, or have sweats, and has no alcoholic or specific history. The appetite was good, the bowels slightly constipated. The urine had a specific gravity of 1018, was acid in reaction, and did not contain albumin or sugar. The blood examination on March 15, 1895, showed hemoglobin, 17 per cent., and red corpuscles, 1,340,000. The red blood-corpuscles showed slight poikilocytosis, and there were megalocytes and microcytes in considerable number. Only about 5 per cent. of the red corpuscles were normal. The white blood-corpuscles were normal and there were no malarial organisms. Inspection showed a well-nourished man, intensely pale, the pallor being of rather a yellowish hue, the subcutaneous tissues were well filled with fat. The heart and lungs were normal, except that the heart sounds were feeble. The spleen was not enlarged, and the liver dulness was normal. There was no abdominal disease, but deep palpation in the area proper for the head of the pancreas revealed the presence of a small swelling. He was placed upon ascending doses of Fowler's solution of arsenic and reduced iron, three times a day, the latter being given in ascending half-grain doses.

On March 26, 1895, the hemaglobin was 10 per cent., and the red blood-corpuscles numbered 760,000 to the cubic millimeter. On the 29th, the hemoglobin was 10 per cent., and the red blood-corpuscles, 548,000. On April 1st, the hemoglobin was 8 per cent.; the red blood corpuscles, 520,000, On April 5th, the hemoglobin wes 8 per cent.; the red blood-corpuscles, 454,000.

The patient died on April 6th. The *post-mortem* showed well-marked rigor mortis, abundant subcutaneous fat, muscles well preserved and very red in color. The bone marrow was chocolate-colored. There was a small, clear effusion in the right pleural cavity. The left pleura was universally adherent and the cavity contained six ounces of clear fluid. The pericardium contained six ounces of clear fluid. The right ventricle was flabby and relaxed, the left being firm and contracted. There were no clots in either ventricle or in the vena cava. A large chicken-fat clot was found in the pulmonary artery. The aortic valves were patent; the mitral valves were slightly thickened. The cardiac muscle was pale, flabby, soft, and cloudy. The pericardial fat showed a tendency to invade the heart muscle. The aorta was pale and unusually soft and elastic, and was pared both longitudinally and transversely with little difficulty. The heart weighed fourteen ounces. The right lung showed extensive gelatinous edema. The peribronchial glands were pigmented and a few of them were calcareous. The bronchi were normal.

The sixth case resulted in recovery, although it was apparently one of pernicious anemia. J. D., aged forty-four, a coal-miner, was admitted to the Jefferson College Hospital January 31, 1895. His father died of enteric fever. His mother was living and well. He had the ordinary diseases of childhood and had always been healthy until three years before, when he began to have a sensation of numbness in his fingers. Four months before he had noticed a similar numbness in the feet and legs, with a sensation of fulness in the stomach and a chilly sensation in the lumbar region. He was markedly anemic. His urine had a specific gravity of 1020, and was acid in reaction, but did not contain albumin or sugar.

On March 13, 1895, an examination of his blood showed poikilocytosis, the corpuscles varying very much in shape. There were numerous macrocytes and microcytes. There was a slight diminution in the number of white blood-corpuscles. The hemogoblin was forty-five per cent., and the red blood-corpuscles numbered 2,500,000. He was given ascending doses of Fowler's solution of arsenic with half a grain of Quevenne's iron, three times a day. On March 30th, the hemogoblin was fifty-eight per cent., and the red corpuscles 3,320,000, with very few poikilocytes. April 12th, the hemogoblin was eighty per cent., the red corpuscles, 4,060,000. April 23d, the hemogoblin was eighty per cent., red corpuscles, 4,400,000. The hematokrit gave ninety-four volume per cent.

I have reported these cases because it seemed to me that each of them possesses considerable clinical interest. The first case shows a very great improvement, and a decrease in his white cells to an interesting degree. The second case, as already pointed out, shows a great increase in lymphocytes, yet no actual increase in white cells, so resembling lymphatic leukemia, and yet not following its usual blood count. The third, that of pernicious anemia, is certainly interesting as manifesting an apparent cure, and certainly a great improvement, although clinical experience shows that a fatal relapse will probably ensue. The fourth also shows a very great improvement, sufficient to justify hopes of cure if the patient has not already come to a standstill. Unfortunately we know too well the fatal history of most cases of pernicious anemia. The fifth presents an instance in which the disease pursued a rather rapid and fatal course, with every characteristic, both *ante-* and *post-mortem.* Finally, the sixth case, like the third and fourth cases, illustrates how a patient apparently in the early stages of pernicious anemia can either be cured or the disease arrested, although, as it is a hospital case, I cannot vouch for his permanent recovery.

In conclusion, I desire to thank Dr. A. H. Stewart for the various blood counts recorded in this paper.

MEDICAL PROGRESS.

Treatment of Gunshot Wounds of the Head.—In 38 cases of gunshot wound of the cranium treated in Bardeleben's clinic, TILMANN says (*Deutsche Mil. Zeitschrift*, 1896, Hft. 1) that the following results were obtained: Out of the whole number, 21, or 55 per cent., recovered; of the 16 in which penetration into the cranial cavity could not be ascertained, all recovered; of the 22 in which the ball had entered the cranial cavity, 5 recovered, or about 23 per cent. Almost identical results were obtained in the 197 cases of gunshot wound of the cranium, which is the entire number of these cases so far treated in the clinic: Eighty-three (42.1 per cent.) died; 114 (57.8 per cent.) recovered; of the 72 non-perforating wounds, but 1 died; of the 125 in which penetration had taken place, 82 (65.6 per cent.) died; 34.4 per cent. ended in recovery. The sixteen in which there was no penetration of the ball were treated simply by a thorough cleansing of the wounded area, wiping out of the wound with dry balls of gauze, and covering it with iodoform, or sterilized gauze, and encasing all with a little cotton and collodion. In two cases in which there was hemorrhage the superficial temporal arteries had to be ligated. The wounds healed within two or four weeks without fever. In one case the wound remained patent, and in one case the flattened ball, which remained embedded, was cut out after complete cicatrization.

Six out of the twenty-two cases in which the ball had penetrated were brought in unconscious and died within six hours. On *post-mortem* there was found to be a slight comminution of the part where the ball had entered with fine fissures about one centimeter in length radiating from the wound of entrance; in one case fine chips of bone were found to be embedded to the depth of five centimeters in the substance of the brain. Three of the six cases that were brought in unconscious were bleeding from the temporal artery, the ligation of which was accompanied by the oozing of brain substance with clotted blood; these died within twenty-four hours. In five cases the middle meningeal artery was wounded; and in two of these cases the first clue to the involvement of the middle meningeal was paralysis on the opposite side of the body, appearing first in from five to thirty-one hours, and inducing death before an operation could be undertaken. In three other cases the primary trephining, with ligation of the artery, was undertaken, without success, however. Death was due in one case to secondary hemorrhage, which took place on the ninth day, just as the bandage was being changed. Of the other cases one patient died of meningitis, and another succumbed to a severe hemorrhage into the cavities of the brain. In seven cases secondary trephining was performed; in two of them, after twelve hours, because of the development of paralysis (one recovery); in three other cases, on account of fever, operation was performed after three days (two succumbed to meningitis purulenta, one recovered); and in one case after two, and in another after nine days, for removal of the impacted ball (both recovered).

Primary trephining is indicated when there is considerable arterial hemorrhage, and if symptoms of lateral paralysis or spasms are present. Later, this operation may be indicated when fever develops with lateral paralyses, and also when the presence of the ball in the wound has been ascertained. Otherwise it is better to wait; for, as a rule, the removal of the chips of bone will be impossible. Under this latter treatment, in five cases in which the ball had penetrated both tables of the skull, five recovered, one even without any operation. The most serious symptom is continued unconsciousness.

Gonorrheal Endocarditis.—A case of endocarditis due to gonorrhea came under the observation of MICHAELIS. A man, twenty-five years of age, in the third week of an attack of acute gonorrhea, was seized with severe rheumatic pains in the finger joints. The metacarpal-phalangeal joints of the third and fourth fingers became much swollen; temperature, 102.4° F. After a few days a scraping, systolic murmur was heard in the aortic region, and on the twelfth day after admission to the hospital, the patient with but a moderate fever succumbed to a fatal syncope. On section a verrucose mass about the size of a hazel nut was found attached to the aortic valve, and beneath this was a rupture. Microscopic and bacteriologic examinations revealed the presence of gonococci. (*Zeit f. Klin. Med.*, 1896, Bd. 29.)

Treatment of Chronic Empyema by Decortication of the Lung.—DELORME (*Gazette Hebdom. de Med. et de Chir.*, No. 95, p. 1129) reports nineteen cases of chronic empyema of from six months' to eleven years' duration, in nine of which the above-mentioned procedure effected either an entire obliteration of the cavity or greatly increased pulmonary expansion. Failure resulted from pulmonary tuberculosis, either unrecognized or following an otherwise successful operation, or from inability to detach the fibrinous covering of the lung.

The cavity should be disinfected for several days before the operation. No special instruments are needed. Those used should be long and blunt. Most of the work can be done with the fingers. The presence of adhesions should be determined before opening the chest-wall, and to avoid shock the operation should be as rapid as possible, and the region of the pericardium and diaphragm avoided. Care should be taken not to penetrate the lung in the first incision through the membrane. Should this occur, a fresh incision should be made. Hemorrhage is slight, when neither parenchyma or visceral pleura is wounded.

In the after-treatment, exercise and pulmonary gymnastics are advisable. When decortication is impossible, the operation must be abandoned, and that of Estlander or Schede substituted.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

THE EFFECT OF DIET AND STARVATION IN MICROBIC POISONING.

THE old saw, "Starve a fever," finds justification in a report made to the Paris Academy of Sciences by Teissier and Guinard, February 15th. As a result of their experiments these gentlemen claim that complete or partial abstinence from food lessens the effects of toxins. Dogs were the subject of their experiments, and the pneumobacillus and the diphtheria bacillus were the germs employed. Twenty-two animals were subjected, while in a starving condition, to injections of toxin in amounts which invariably killed the control animals. Four of these recovered, and in those which died the intestinal lesions and those of the liver and spleen were less marked in the starving animals than in those which had received food. To obtain this increased power of resistance against the poison it is necessary that the animal should suffer lack of food for some time. If the starvation diet has continued only five or six days, and if, owing to surplus fat, the animal is able to resist the effect of starvation, he falls a prey to the toxin as readily as an animal receiving food.

Two hypotheses have been advanced to explain this interesting phenomenon. One presupposes that the cellular elements of the body being starved, as it were, are ready to seize upon and assimilate whatever is presented to them, and that they destroy the toxins before they have time to act. According to the other hypothesis, the toxins act slowly or not at all, because the organism in its starving condition does not supply the elements whose presence is essential for the production of the active poisons. The second hypothesis seems to the investigators to be the better explanation.

SOME FURTHER CONSIDERATIONS OF HOSPITAL AND DISPENSARY ABUSES.

MASQUERADING in the garb of charity, the aim of most hospitals is to attract large numbers of paying and curable patients. A fair pecuniary return for services and a low death-rate make the sleek philanthropist rub his hands in glee.

The real autocrat of the hospital is the superintendent. However kind-hearted he may be by nature, he is so fettered by rules that, to secure admission, an ability to pay on the part of the patient becomes the prime requisite, real need a secondary consideration. The admitting physician gives to the financial status of the patient no attention, and to his real need, little. He is looking for quickly curable cases that his service may be full and brisk and his death-rate low. Between the two, *viz.*, the automaton of adamantine charity and the man of science, God help the poor man who is almost moribund or a chronic and uninteresting invalid!

In various ways, subjected to no real discrimination, about 75,000 people yearly avail themselves of nearly gratuitous medical and surgical attendance, medicine, surgical dressings, nursing, board, lodging, and washing in the hospitals of New York City.

The prime idea of managers of dispensaries is to report yearly the greatest possible number of patients treated, prescriptions filled, and visits made by their district physicians. Largely dependent for support, as most of them are, upon voluntary contributions, the more show they make of their indiscriminate giving, the more money will they receive. It naturally follows that in less than half our dispensaries only a mere pretense of inquiry is made into the real necessity of the patient. In almost none are adequate measures employed to detect and prevent fraud. In few, if any, is the doctor vested with any discretionary power. Thus rich and poor alike find welcome shelter under, not as they would like to think, the ample cloak of charity, but what really is the pall of self-respect and the shroud of honor.

What does the vainglorious Charity King care if the sick, by subterfuge and deceit, and with his connivance and assistance, cheat the poor doctor of his modest dues? Will not the patient, by this crime, have more money with which to buy of the Charity King his high-priced coal and gas, his flour and sugar, and be readier with the exorbitant rent for his unsanitary and stuffy rooms? As long as he has his own servile physician at his beck and call, what does he care for the rank and file of the profession? For the meek and devoted physician, whom he makes give away his brains at his pet dispensary, he has no more respect than for his butler or coachman; and why should he? Does he not remember how this same man struggled, nay, grovelled, for the appointment? How he has for years willingly worked for his own impoverishment and debasement? How, when that has been effected and he has died in the harness poor and devoid of self-respect, a hundred other men have fallen over each other in their eagerness to wear the shackles? Why should we look for respect when our own self-respect falls so low? Why grumble when the Charity King, to intensify the refulgence of the benevolent halo surrounding his emphysematous head, gives freely what are not his, our brains and very life!

Hospital and dispensary managers are disinclined to allow the physicians any credit for the institutions' benefactions. They unanimously claim that the physician is fully paid for his services, if not in money, by professional experience thus gained. Does not the physician tacitly acknowledge this compensation by his eagerness to secure the position and year after year do the work uncomplainingly? Stripped thus of his only glory (for how many dispensary physicians will acknowledge themselves actuated in their work by charity alone), the tool of professional philanthropists, he is compelled by his misguided policy to prostitute his profession, to give his brains to the undeserving, to take the very bread from his own and his brother's mouth, and dig his own material grave. What bosh to talk about respect or self-respect or to complain of being treated like a chattel! Haughty Pharisees hoisted aloft by gifts not theirs and servile physicians patient at their suicidal work—what a sight is that! And yet it is at our very doors, under our very eyes.

And the clinics? What of them? They are the most flagrant offenders of all! At our nine medical schools there are some two hundred clinical professors, lecturers, and instructors, who must have clinical material at any price, and in any way. It comes from hospital wards, from dispensaries, from their own practice, from their neighbors' practice. If not in town, from out of town. In the sharp competition, a rare case is welcomed though in affluent circumstances; interesting cases are sought out and treated gratuitously, even if well-to-do, while the uninteresting pauper is neglected or referred to a dispensary. Well-to-do patients are sent by country and city doctors to clinics to get skilled advice free, when they can well pay moderate fees. Patients themselves, by their own intuition, come to clinics for the free opinion of the "Professor," and perhaps for free treatment, and generally get both, although in comfortable circumstances.

Patients come from country and city to consult distinguished specialists who, instead of turning them over to younger, less renowned men when they find they cannot pay large fees, relegate them to their clinics where they get advice and treatment gratis.

Thus in hospital, dispensary, and clinic the baneful dance goes on until medical charity has become a disgrace and medical honor a byword. Looking beneath the surface, aside from its medical aspect, this craze for getting something for nothing, allowed by us who lose, encouraged by those who lose nothing, betokens a state of social and moral rottenness truly appalling.

Is there no remedy? Appeal to the public would be useless, as long tolerance and encouragement have led it to regard gratuitous medical attendance as its right. Appeal to the Charity Kings would be futile, as long years of servility on our part makes protest impertinence. Unanimous, persistent, and concerted action on the part of physicians is unknown and impossible, so thoroughly is our professional structure undermined by servility and selfishness. The rising generation of physicians will not help us, trained, as they are by precept and example, to lax ethics and commercial ways. Some ray of hope might come from future students if, by example and by plain, honest, undergraduate instruction, the hardships, trials, temptations, and possible triumphs of professional life were depicted to them and they were shown the necessity of attaining and holding to a high ideal as alone conducive to lasting contentment and self-respect.

If we turn in our despair to official organizers of charity we see them thrown into spasms of virtuous indignation at the distribution of a few loaves and fishes by a sensational newspaper and the temporary housing of a few vagrants, during a freezing blizzard, by an organization of Christian workers. Such antics are amusing to us who, for twenty years, have seen unchecked pauperization attain gigantic proportions under their very noses. Their affectation of infallibility in dispensing charity may please themselves but does not deceive others. Their claim, that indiscriminate giving is degrading and should be stopped, is right, but why should they pounce with such furor upon a single kindly, but perhaps unwise, act of unorganized charity, while conniving at the daily misdemeanors of organized charity? Why champion the cause of butchers, bakers, and lodging-house keepers and ignore the depredations inflicted upon a learned and bevolent profession.

No sane person would admit that, in 1893, one-third of our population, 1,800,000, were paupers. Yet, in that year, our city dispensaries treated 680,789 patients. That a large number of these recipients were unworthy does not ruffle organized charity in the least, but, had the donations been food or shelter instead of doctors' brains, what a mighty howl would have gone up.

Indiscriminate giving is degrading and demoralizing to the recipient, and its unchecked growth foreshadows a social plight from which all right-minded citizens should recoil with horror. Instead, therefore, of straining at gnats, let charity organizers at once attack and abolish an evil most pregnant with danger to good citizenship.

No institution should be allowed to give alms, whether food, fuel, shelter, or others' brains, unless it is in position to prove, in each individual case, that the recipient is worthy. That would mean the employment of a detective force commensurate with its sphere of action. That requirement and a full accountability for indiscriminate and improper almsgiving would do more to restore and preserve an honest and self-respecting citizenship than anything else, and should be speedily embodied in some legal enactment.

Meanwhile there is something that even the humblest member of the profession can do to mitigate the present deplorable state of affairs. He can treat poor patients gratis at his office, and patients with very moderate means for what they can afford to pay, however small the fee. Thus will his professional self-respect be retained. Then will his charity be true charity and his consideration will be rewarded by the gratitude of patients not yet calloused by beggary nor debased by imposture. In this quiet way some inroads could be made upon this great injustice to the profession and evil to the community. The more sweeping measure, as has been previously suggested in the NEWS, would be to cut off the revenue of the dispensaries by withholding city aid, and make it an illegal act for any dispensary to accept money from a patient.

ECHOES AND NEWS.

The Louisiana State Board of Health.—This Board has announced that it will supply antidiphtheritic serum to poor patients free of cost.

The Willard Parker State Hospital.—William L. Russell of Bay Shore has been appointed first assistant physician in the Willard Parker State Hospital at a salary of $2000.

A Nurses' Home in Worcester, Mass.—Mr. Edward C. Thayer, of Keene, N. H., has offered to erect, at an expense of not less than $35,000, a home for the nurses employed in the City Hospital in Worcester, Mass.

Fined in Philadelphia for Expectorating.—One passenger has been arrested and fined $5 in Philadelphia for persistently spitting on the floor of a street car in that city, though requested by the conductor several times to cease doing so.

Concentration of Doctors' Offices.—Denver, Col., is to have a building 125 feet long by 50 feet deep and two stories high, to be devoted exclusively to doctors' offices. Twenty physicians can be accommodated, and there will be a common operating-room fitted up in the most approved manner.

The Mecca Pilgrimages.—The Government of India has taken the proper course of forbidding all pilgrimages to Mecca from India for a year. The announcement to this effect was officially made to the recent Sanitary Conference at Venice. The French Government has also prohibited pilgrimages in Algeria and Tunis.

A Remarkable Case of Mercurial Poisoning.—A case is reported from Germany in which a thermometer suspended over a heated stove burst, and the mercury, falling on the hot surface, became vaporized and poisoned two children who were sleeping in the room. They eventually recovered.—*Med. Press.*

The New York School Inspectors.—The 150 medical inspectors of schools have been appointed. Forty-one of the doctors are men who have served on the summer corps. Only three physicians who passed the civil-service examination have declined. One successful man is a negro, who will be assigned to the one school that is devoted exclusively to colored children.

The Hoagland Laboratory.—This *quasi* post-graduate school of Brooklyn announces its annual courses in pathology and bacteriology for the months of April and May. Drs. J. M. Van Cott and E. H. Wilson are the directors in those departments of the Laboratory. Dr. J. H. Raymond, secretary, should receive applications.

Marking of Oysters.—A discussion took place in the House of Commons last week regarding the question of oysters and disease. It was stated that the demand for oysters in England has fallen off by three-fourths. A resolution was introduced declaring that the selling of oysters brought from foreign layings, without declaring their origin at the time of sale and without plainly marking such origin, be a penal offence.

New York Board of Medical Examiners.—Drs. William Warren Potter of Buffalo, Maurice J. Lewis of New York, and William S. Ely of Rochester have been appointed their own successors on the State Board of Medical Examiners, representing the Medical Society of the State of New York. Drs. James Willis Candee of Syracuse, John Mallory Lee of Rochester, and Asa S. Couch of Fredonia were similarly reappointed on the board representing the Homœopathic Medical Society.

Superintendents of Hospitals for Infectious Diseases.—The old writers had a word of Greek origin which they found convenient as a designation for medical men and nurses who took charge of patients having infective maladies; the original of the term being παράβολος, venturesome. For modern uses it may become convenient to shorten up some of the long-winded designations or titles that are applied to our contagious *confrères*, and term them our parabolanic physicians.

Tuberculosis Among the Negroes.—The South Carolina State Board of Health at its recent meeting decided to issue a circular to all colored teachers explaining the ravages of consumption among the colored population, and showing that the most fruitful cause of the spread of this disease was the habit of expectoration by consumptives on the floors of school buildings and elsewhere. The teachers will be warned and urged to take every precaution possible to prevent the further spread of the disease from this cause.

Mutter Lectureship of the College of Physicians of Philadelphia.—The next course of ten lectures instituted by the late Professor Thomas Dent Mütter, M.D., LL.D., on "Some Point or Points in Surgical Pathology," will be delivered in the winter of 1899–1900 before the College of Physicians of Philadelphia. The compensation is $600. The appointment is open to the profession at large. Applications stating in full the subjects of proposed lectures must be made before October 1, 1897, to Committee on Mütter Museum, John H. Brinton, M.D., Chairman, northeast corner Thirteenth and Locust streets, Philadelphia, Pa.

Charles James Fyfe, M.D.—An English naval surgeon, was killed during the expedition of the British against the bloodthirsty king of Benin. He was surgeon to the "St. George," man-of-war, and was in the act of caring for a wounded officer of marines when he was shot dead by the enemy. He was a young officer, and had been only four years in the service. The *British Medical Journal* does not fail to remind its readers that he and his surgical comrades are rated as "non-combatants"—praised as "brave civilians" when they fall on the field of battle—but are accorded none of that official recognition which they have been for years urging the government to grant.

An Epidemic of Trachoma. — Eastern and Western Prussia, Posen, and Silesia have recently been visited by an epidemic of trachoma, and the cases are very numerous, especially in some districts near the Russian frontier, where the general standard of living is low. The reports of the medical officers of health show that in the district of Johannesburg there are 2343 patients, and in the district of Lyek 3913, of whom 994 are in the town of Lyek, the remainder being in the country. Experts are to be appointed by the Government to travel through the infected districts and to attend the poor in conjunction with the local medical men.—*London Lancet.*

Free Training in Experimental Physiology.—Exceptional opportunities for training in physiology are presented by the Department of Physiology in the Harvard Medical School, Boston, which offers positions for four qualified men without charge. The explanatory circular may be had of Prof. Henry P. Bowditch at the school. Applicants must possess an elementary knowledge of physiology, and a sufficient training in one or more of the biological sciences. The chosen candidates "will give the mornings of the collegiate year to research, and the afternoons to the direction of undergraduate students in experimental physiology, under the supervision of a professor in the department."

A Scandal at Monsignor Kneipp's Water-cure.—According to the *British Medical Journal*, February 29, a scandalous state of things in the management of Pfarrer Kneipp's establishment at Wörishofen has been disclosed by a lawsuit brought against one of the male nurses there by the parents of a former patient. The patient, it appears, was a weak-minded young girl with a leaning to nymphomania. She had previously been placed in an asylum, but her parents had removed her from it and brought her to Kneipp's establishment, "confiding in the sanctity of the place." It seems almost incredible that the night nurse allotted to this poor half-witted creature was a young man; yet such is the fact. For eight or nine nights she was left alone with him, until one night, when he apparently ill-treated her, her screams brought in another male nurse, to whom the first one then resigned his charge. After some months the poor girl left Wörishofen, and in due time gave birth to a child.

A Druggist Prosecuted for Substitution.—Fairchild Bros. & Foster have taken action in the Court of Chancery of New Jersey, against Chas. Holzhauer, a druggist of Newark, for fraudulently dispensing some preparation not Fairchild's, when Fairchild's Essence of Pepsin was specified. These preparations so dispensed and sold as and for Fairchild's Essence of Pepsin differed materially in chemical composition and physical properties from the latter, and also contained salicylic acid. The motion for injunction was granted without any defense on the part of Holzhauer. This action against substitution must receive the cordial endorsement of the entire medical and pharmaceutical profession, and we have reason to believe it is equally satisfactory to all honest druggists. The best class of druggists deplore this evil, and would welcome any general and decisive effort to rid the trade of it, for they realize that this practice is one which is prejudicial to the best interests of the drug trade in every way; and furthermore, the honest druggist naturally recognizes in this practice an illegitimate and fraudulent competition, while the wrong to the physician and the public cannot be overestimated.

An Antivivisectionist.—That eminent scientist and widely recognized authority on the theory, practice, and aim of surgery, Mr. Jerome K. Jerome, is an ardent foe of vivisection. In *To-day*, his own London weekly, he says: "If two phrases occurred to me, one of which would not give offense to the vivisectionists, and of one which would, I should unhesitatingly choose the latter. I do all I can to help to create among the public a growing horror and detestation of vivisection, and of those who support and advocate vivisection." The first sentence is more than a bit shaky as regards the structure of its antithesis, but that is too small a matter to notice, as Mr. Jerome is not quite so eminent as a literary man as he is in the other ways mentioned. What really deserves attention is the mistake he will make by an intentional resort to cruelty to vivisectionists. Can he not see that the shrieks and quiverings of creatures, even so abhorrent as they, will grievously shock some observers and irremediably brutalize many others? Whether he hurts them with a scalpel or his grammar the result will be the same, and he will hinder, not advance, the good cause to which he is devoted.—*N. Y. Times.*

The Bubonic Bacillus in America.—The bacillus of the bubonic plague has been subjected to experimental examination by Dr. E. H. Wilson, Chief of the Bureau of Bacteriology in the Brooklyn Health Department. The practical purpose of the study was to see what should be done to protect this port from infection through goods imported from India, but the scientific value of the results consists in the addition to the limited information among scientists as to the nature of the bacillus. Conclusions: (1) The thermal death point of this organism is one or two degrees higher than that of the majority of pathogenic bacteria of the non-aperulating variety. (2) Differing widely from cholera, sunlight and desiccation cannot be relied upon to limit the viability of this bacillus under commercial circumstances. (3) Rags, mails, ballast, and general merchandise coming from infected ports should be subjected at either the port of departure or the port of entry to a thorough system of disinfection. Experiments in regard to the effects of chemical disinfectants have been made in the laboratory only with carbolic acid. It has been found that an exposure for two hours to a one-per-cent. solution of carbolic acid sufficed to destroy the life of the bacillus.

The Academy of Medicine and the New Charter.—At the meeting of the Academy of Medicine the report of the committee appointed to investigate the subject of the Health Department in the charter of the Greater New York was presented. It is signed by Drs. Edward G. Janeway, President of the Academy; Stephen Smith, Joseph D. Bryant. George G. Wheelock, and Prince A. Morrow, secretary. The report said, the committee was not inclined to advise a change in the charter in regard to extraordinary powers, which were sometimes necessary. Should occasion arise, public opinion would take from the board its authority. Moreover, the Academy should and would be the first to demand such action. The committee suggested only such changes as relate to the discrimination made against physicians in the appointment of the President of the Board of Health and the abolition of the Coroner's office in favor of a modification of the Massachusetts system. They asked that the Board of Health consist of three Commissioners, appointed by the Mayor, two of whom shall be practicing physicians of not less than ten years' standing; that the third Commissioner be a reputable citizen; that the Health Officer of the Port be *ex officio* a member. Some opposition was made to immediate adoption, and the report went over until the next meeting.

Obituary.—Dr. Clark Wright died March 16th at his home in New York, in the thirty-eighth year of his age. Dr. Wright, son of the late Dr. Clark Wright, was born in this city, and was graduated from Yale College. He studied medicine at the College of Physicians and Surgeons of New York, and completed his studies in London and Germany, remaining abroad several years. He was connected with the Roosevelt Hospital Out-Patient Clinic, and had established a considerable practice. He leaves a wife and one little daughter.—Dr. Arnold Scott of Philadelphia, aged sixty-nine years, died March 18th, on a street car, of heart failure. He was born in Wetzler, Germany, and his ancestors were associated closely with the historic characters of the empire. As lieutenant he served with distinction in the rebellion of 1848, when Southern Germany struggled for supremacy against the Northern States. He studied medicine in Germany and came to this country in 1866.—Dr. Abel Wares, of Haverhill, Mass., died March 15th, aged sixty-nine years.

He was Grand Treasurer of the Supreme Order of the United Order of the Golden Cross of Massachusetts. He leaves a wife and a son.—Dr. James Etheridge died at Macon, Ga., March 14th, just as the surgeons were about to operate on him. They examined him before he was placed on the table, and they decided that he could take an anesthetic. Almost at the very instant it was applied he expired. A *post-mortem* showed that death was caused by paralysis. Dr. Etheridge was a prominent physician of Macon.

CORRESPONDENCE.

EXPECTORATION ORDINANCE AT SARANAC LAKE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I herewith inclose copy of "Ordinance Concerning Expectoration," adopted by our Board some months ago:

"SECTION 1.—All persons who expectorate in consequence of any disease of the air passages (lungs, throat, mouth, or nose), are positively forbidden to spit or discharge such expectorated matter upon the floor of any house, store, church, schoolhouse, or upon any sidewalk, or in any dooryard, or other place where such matter may be the means of communicating disease to other persons.

"SECTION 2.—Any person who shall violate the first section of this ordinance shall be liable to a penalty not exceeding $5 for the first offence, nor more than $25 for a subsequent offense, which penalty shall be imposed by and at the discretion of the Board of Health.

"NOTE.—Hotels, inns, and boarding-houses should provide suitable cuspidors for the accommodation of their guests. Cuspidors should be thoroughly cleansed and disinfected daily, and should contain a small amount of germicide solution.

"Persons who have occasion to expectorate when on the streets should carry small pieces of cheesecloth, which, after being used, must be preserved, and burned with as little delay as possible. Chinese paper napkins or toilet paper will answer a similar purpose. The casting of any of these aside, after use, where they may affect others, will be regarded as a violation of the ordinance.

"CAUTION.—Handkerchiefs should never be used to receive expectorated matter. If so used, they must be boiled, or soaked in a germicide solution, with as little delay as possible, and never be put with other articles to be laundried."

This ordinance is vigorously sustained by our people. Of course, with newcomers we have to do missionary work, but a notice usually brings the transgressors to a sense of duty, with a promise to obey in future.

Your recent editorial and reference to Dr. Trudeau's work was admirable and very gratifying to us here. This is a great work of education. Nothing can be accomplished except by persistent and untiring work.

Yours very truly,
E. S. MCCLELLAN,
Pres. Board of Health.

SARANAC LAKE, N.Y.,
March 18, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE WIDAL-GRUNBAUM SERUM-TEST BY THE BOARD OF HEALTH—ANTISTREPTOCOCCIC SERUM IN SEPTIC CONDITIONS—MEETING OF THE SECTION IN GENERAL MEDICINE OF THE COLLEGE OF PHYSICIANS—FOOD AND DRINK ADULTERATION—NEW SITE FOR THE MUNICIPAL HOSPITAL—DR. S. WEIR MITCHELL—POPULAR LECTURES AT THE POLYCLINIC.

PHILADELPHIA, March 20, 1897.

IN order to test the practical usefulness of the Widal-Grünbaum serum test in cases of enteric fever, the Philadelphia Board of Health has offered the services of the Bacteriologic Laboratory to examine and report on samples of dried blood from suspected cases of this disease received from the physicians of this city. A circular letter to this effect, together with a card of instructions and outfit for collecting the blood sample, was sent to the profession generally on the nineteenth instant. In view of the fact that the test is still in an experimental stage, explicit information is desired from those sending samples as to the course of the disease, as well as to any discrepancy between the result of the laboratory diagnosis and the clinical aspects of the case in question.

The treatment of septic conditions by the use of antistreptococcic serum was thoroughly discussed at a meeting of the Section on Gynecology of the College of Physicians devoted to this topic, on the evening of the eighteenth instant. Papers were presented by Dr. Barton C. Hirst, Dr. J. M. Baldy, Dr. G. E. Shoemaker, Dr. R. C. Norris, Dr. E. P. Davis, and Dr. J. B. Shober. Dr. A. C. Abbott, in opening the discussion, traced in an interesting manner the development of serum therapeutics, and outlined the process of manufacture of any given serum for the treatment of a condition due to a given germ. The general attitude of the papers read at this meeting, while not distinctly deprecatory to serum-therapy in septic conditions, left one with the impression that advance must be made both in the preparation of the serum and in our understanding of the cases in which its employment is indicated, before its value as a therapeutic agent should be accepted.

At a meeting of the Section on General Medicine of the College of Physicians, held on the sixteenth instant, Dr. S. S. Kneass exhibited a stained specimen of the serum reaction in enteric fever, and read an instructive paper on this subject, detailing a number of instances in which he had applied the test. Dr. Alfred Stengel, in the discussion which ensued, spoke of a case in which the diagnosis lay between acute miliary tuberculosis and enteric fever, and which gave a negative reaction with the serum test. The negative value of the test was later substantiated in this instance by the *post-mortem* finding of miliary tuberculosis. Another valuable communication read at this meeting was a study of anomalies of the kidney, by Dr. J. C. Wilson, who also showed several specimens illustrating his paper, and exhibited a case bearing upon the subject.

According to the recent report of the chemist of the Health Board, Mr. William C. Robinson, extensive adulteration is being practised with regard to many brands of tinned goods now on the market, which, even if not of a distinctly poisonous character, must at least be considered to contain substances of a deleterious nature. To those who favor a certain widely heralded and popular make of beer it may also be a matter of some interest to recollect that with their favorite beverage they likewise consume a not inconsiderable quantity of hydrofluoric acid, added to the beer to prevent fermentation other than alcoholic. Apropos of the latter, a rigid and systematic drink inspection is recommended in the future. Another official report of interest to medical men is that of the Chief Milk Inspector of the city, Mr. Byrnes, who vigorously condemns the custom of serving bottled milk and cream to consumers by the dealers. Bottled milk, he contends, is the best medium by which the germs of such diseases as diphtheria and scarlet fever may be disseminated, and, inasmuch as many of these bottles must find their way into infected dwellings, and are even in some instances taken into the sick-room itself, the custom probably accounts for not a few of the obscure cases of infectious diseases, for which no apparent cause seems to exist.

The absurd proposition, fostered by the committeemen in charge of the subject, to build the new Municipal Hospital on a patch of malarious swamp land fronting the Delaware river, on the outskirts of the city, has fortunately been defeated by the action of the City Council in the matter, so that for the present, at least, there is but little likelihood that this institution will be relegated to the marshes—a location which it would seem was considered by those charged with the duty of selecting a new site for the hospital as quite in keeping with the infectious character of the cases to be treated in the projected hospital. It has been aptly remarked that, in event of the City Council accepting the recommendations of the "Swamp Committee," it would be the plain duty of the Board of Health to promptly board up the new hospital as soon as it was built, and to forbid the reception of patients; and, viewed from the Board's sanitary standpoint, this is precisely the action they might be expected to take.

Dr. S. Weir Mitchell, who has recently sailed for Europe, expects to remain away until the late fall. He will spend some time on the Continent, returning to spend the autumn in the Scottish Highlands, where he has taken a country house. His return is looked for in the latter part of October.

A course of seven lectures on topics of popular interest is announced by the faculty of the Philadelphia Polyclinic. The lectures will be delivered in the college amphitheater, the subjects being as follows: March 24, "Prevention of Consumption and Care of Consumptives," by Dr. S. Solis Cohen; March 26, "Hygiene and the Laws of Health," by Dr. Henry Leffman; March 31, "Surgical Emergencies," by Dr. Thomas S. K. Morton; April 2, "The Roentgen-Ray Apparatus and Skiagraph," by Dr. Max J. Stern; April 7, "The Nursing of Fevers," by Dr. Judson Daland; April 9, "Developmental Needs of Children," by Dr. J. Madison Taylor; April 14, "Mother and Child," by Dr. Edward P. Davis. As this series of lectures is intended for popular instruction on medical topics, admission will be free, and the general public is invited to attend.

OUR PARIS LETTER.

[From our Special Correspondent.]

THE PATHOLOGY OF MORVAN'S DISEASE—RANVIER'S STUDIES ON THE CICATRIZATION OF WOUNDS—FRANCK'S OBSERVATIONS ON THE RESULTS OF COMPRESSION OF THE HEART—THE EFFECTS OF POISONS ON THE HEART AND BLOOD-VESSELS—SCIENTIFIC DEMONSTRATIONS POORLY ATTENDED BY THE PROFESSION IN PARIS.

PARIS, February 24, 1897.

At the *séance* of the Société Médicale des Hopitaux de Paris on February 12th, Marinesco and Jeanselme presented a very interesting contribution to the study of that much-discussed question, the pathology of Morvan's disease. Following the lead of Charcot, it has been the custom here, until quite recently, to regard the disease always as an abortive, incomplete, atypical form of syringomyelia. In the East, especially at Constantinople, the similarity of the symptoms ascribed to Morvan's disease, especially its completely anesthetic mutilating panaris, and the fact that Morvan, in a country district of less than 50,000 inhabitants, found some fourteen cases of it to describe, led them to suspect indigenous but deteriorated forms of leprosy. There where leprosy is so common and its varying characters so familiar, the thought does not seem so strange as it would farther West. Not long ago, Zambuca of Constantinople, found, in what was symptomatically a typical case of Morvan's disease, the cavity in the cord that would be expected in syringomyelia, but he found, in addition, in the broken-down material of the cavity Hansen's lepra bacillus. This attracted a great deal of attention here, and even led to some doubts as to the etiology of even the more typical cases of syringomyelia.

Marinesco reported the careful autopsy of a typical case of Morvan's disease on which Charcot, in 1890, based one of his clinics, while Jeanselme reported the necropsies of two cases of the disease made in Bretagne, where Morvan's original study of the disease was made. Marinesco found the usual lesion of syringomyelia, a cavity in the cord, more or less triangular in shape, in this case, and extending from the sixth cervical to the sixth dorsal roots. The part involved was almost entirely the left posterior horn, the anterior horn being left almost completely intact. The interesting aspect of the pathologic anatomy for Marinesco lies in the fact that lesions of the left posterior horn should give the trophic troubles incident to Morvan's disease, localized entirely in the left hand. The inference is that the medullary lesions of Morvan's disease have their seat in the posterior horns, and that it is here as a consequence that the trophic centers for the integumental and skeletal tissues of the extremities are to be found. A careful bacteriologic investigation did not disclose the presence of bacilli. The cavity in the cord was, as is usual in syringomyelia, the result of a gliomatosis of the periendyma, the process starting seemingly in the canal and spreading to the posterior horns.

Jeanselme reported that he had not been able to find bacilli in the anesthetic spots either over- or under-pigmented, as they occur in Bretagne, the home of the disease. As Hansen's bacillus is not often found in the trophic lesions of leprosy, however, Jeanselme did not consider that he could base any satisfactory conclusion on his negative results.

I spoke some weeks ago of Ranvier's studies on cicatrization of wounds of the cornea, especially of healing by first intention. With the further development of the subject, Ranvier announces his theory that healing of cutaneous wounds, where suppuration does not intervene, is accomplished by a similar process to that in the cornea. Epithelial cells from the upper cutaneous layers, surrounded by agglutinative material, are forced out partly by the mechanical contraction of the cut tissues, and serve to bridge over in a few hours the gap made by the wound. This new material, if undisturbed, gradually acquires the character of cicatricial tissue though not to the extent that is observed, when, after suppurative or other disturbing processes, there is a real formation of new connective-tissue. In the demonstration of repair of wounds in the cornea, Ranvier shows a set of slides where, with the processes of repair nearly completed, there are scattered here and there in the immediate neighborhood of the wound little islets made up of epithelial cells—the epithelial whorls that are usually said to be so characteristic of epithelioma. Ranvier frankly states that, as for himself, given some of these slides and asked to make a diagnosis of the case from which they were taken, he would almost inevitably conclude that there was present an epitheliomatous process. The microscopic diagnosis of epithelioma, especially in the serious cases of suspected utero-cervical epitheliomata, has been difficult enough without having to face the possibility that surgical manipulations intended to be depletory may have led to the production of cicatrical appearances, that even in perfectly benign cases may simulate all the appearances of malignancy.

On Saturday, February 13th, Professor Francois Franck gave at the Charité, by invitation of Professor Potain, a demonstration of the results of his recent observations on the accidents caused by compression of the heart in the pericardium. In pericardial effusion it is the pressure of the effusion upon the auricles that determines death in the fatal cases. As soon as the pressure of the effusion confined within the pericardium exceeds the venous blood-pressure tending to drive the blood into the auricles, death is inevitable. Three external factors delay the fatal result in practice: (1) As the pressure increases upon the auricles blood accumulates in the veins, venous blood-pressure rises, and the counter pressure is overcome for a time at least; (2) thoracic aspiration, even when only normal, tends to relieve, at certain phases of respiration, the pressure exerted upon the auricles by the effusion, and aids the venous blood-pressure to overcome it; (3) when dyspnea supervenes, thoracic aspiration becomes more pronounced, because of the bringing into play of the supplementary muscles of respiration, and with the deeper respirations there is relief of the counter pressure upon the auricles. In some of his experiments, Franck has obtained very perfect specimens of the pulsus paradoxus. The whole subject is very interesting, as showing the intimate relations between cardiac activity and respiration, and demonstrating that the phenomena of dyspnea, though occasioned by maloxydation of the blood, are not by any means merely the symptoms of a morbid process, but are also nature's compensatory media for helping out a laboring heart.

Professor Franck is giving at the College de France a series of demonstrations of the effects of poisons upon the heart and blood-vessels. His recent demonstrations that the action of the systolic poisons, digitalin and strophanthin, was similar to that produced by direct electric or mechanical stimulation of the myocardium, was a very convincing bit of physiologic therapeutics. There would seem to be no room left for doubt, after seeing the very similar effects produced, that digitalin was a very powerful, direct, cardiac-muscle stimulant. Quite recently, at the end of one of his demonstrations, the heart of an animal exposed for the demonstration stopped beating under the influence of a large dose of chloral. It is just the condition of affairs that occurs in the sudden cardiac accidents of chloral or chloroform, only here there was every assurance that the heart was not merely beating very slightly, but was absolutely stopped. For over two minutes no attempt was made to resuscitate it; then regularly repeated electrical stimulation was tried. After some minutes the heart took up its work for itself once more, and life went on. One cannot help but wonder if the application of electricity will not yet come to the relief of the dread cardiac accidents of anesthesia.

An American medical student cannot help but think that if series of demonstrations, such as one sees with Ranvier and Franck and Henneguy, at the College de France, were being given in a crowded medical center in the United States they would be better attended than they are here. Not more than a dozen people, sometimes even less, go to such demonstrations here, with 5000 medical students and an overcrowded medical profession in Paris. Curiosity, rather than scientific interest, seems to attract people. Just across the hall from Franck's lecture-room a series of lectures are being given on "Realism in Modern French Literature," and the lecture-room is so overcrowded that to get a seat one must go nearly an hour beforehand. The only one of the medical lecturers at the College de France whose lessons are well attended is Janney, who is lecturing on "Experimental Psychology." As his lectures include observations on hysteria and suggestibility, and are illustrated at certain times by patients at the Salpétriére, they attract a good deal of attention from non-medical people.

Here in Paris, as everywhere else, the dread of overhanging examinations, more and more specialized and extended, keeps the medical student effectually in the narrow road of direct preparation for the answering of questions. Except for anatomy, the quiz system practically does not exist, so that a French medical student has more chances of drawing his medical inspiration from the lips of a master in the art, rather than from a quiz master. But it seems too bad that the broadening influence, inevitably the result of contact with the makers of science, should not have chance to exert its sway, because of the haunting dread of examinations to come. They were once meant to show how much the student knows; they have become the reason why he seeks knowledge in certain directions, and the initiative faculty perishes ignobly.

MUCOUS SEPTICEMIA—THE EFFECT OF DIGITALIN IN ASYSTOLE AND CHEYNE-STOKES' RESPIRATION—EIGHT GRAMS OF QUININ SULFATE WITHOUT DEATH—PALPATION OF THE LUNG THROUGH THE PLEURA.

AT the session of the Academy of Medicine, held February 16th, a communication from **BABES** was read on "Mucous Septicemia." This disease, as described by him, is characterized by a facial paralysis, anemia, a light fever, and progressive weakness, terminating in death. The disease is an infection of the blood by a mucin-producing microbe, which, either as the result of a special faculty, or because of favorable conditions, is able to bring about a mucoid transformation of the blood during life. Babes was unable to produce this transformation in the blood of animals experimented upon, although the germ is pathogenic for animals as well as for man.

MERKLEN read a paper before the Medical Society of the Hospitals, February 12th, on asystole and Cheyne-Stokes' respiration. He had the care of two patients suffering from arterio-sclerosis, with attacks of asystole, due to chronic myocarditis. In one of these patients Cheyne-Stokes' respiration came on suddenly twenty-four hours after the administration of one-fifteenth of a grain of crystalized digitalin. Death followed some hours later. The other patient recovered, though asystole and Cheyne-Stokes' respiration continued for six weeks, and appeared to be increased by the digitalin, but was considerably improved by hypodermic injections of morphin, which seemed to neutralize the effects of the digitalin, calming the anxiety and restlessness of the patient and regulating, apparently, the respiration.

GUINON related an instance in which a man, with suicidal intent, took *eight grams, about 120 grains, of quinin sulfate.* There was a profound collapse, with cold extremities, complete deafness, and blindness. The patient recovered.

COMBY reported that there were treated during 1896, at the Trousseau Hospital, 500 cases of scarlet fever, of ages from ten months to fourteen and one-half years. The mortality was 11.6 per cent., or, deducting fifteen cases which were transferred from the diphtheria ward, the mortality was 8.8 per cent.

At the session of the Surgical Society, held February 17th, **LEJARS** reported two cases of the *stripping up of the pleura.* One patient was fifty years of age, and suffered from pulmonary gangrene. Over this area, as determined by auscultation and percussion, about eight centimeters (three and a half inches) of the fourth, fifth, and sixth ribs were resected. The costal pleura was without difficulty separated for a distance of a finger's length, and through this loosened pleura an area of induration could be made out in the lung. A small incision was made, the finger introduced, and by direct palpation it was ascertained that in the center of the indurated area there was a cavity filled with a bloody, putrid fluid. The lung was drawn up close to the wound and fastened in this position; pneumothorax was thus avoided. The gangrenous focus was evacuated. The patient failed rapidly, and at the autopsy presented bilateral sclerotic kidneys.

In the other case, one of gangrene of the lung, secondary to pneumonia, localized in the lower lobe of the right lung, in a patient aged thirty-three, the eighth, ninth, and tenth ribs were resected for about seven centimeters (two and three-quarter inches), and the costal pleura was separated as far up as was possible. Palpation did not reveal a distinct area of induration, and the pleura, which was adherent at this point, was incised. Intrapleural examination by the finger also failed to find a focus. The parenchyma of the lung was incised for a distance of five or six centimeters, but nothing was found. The patient died in a short time. At autopsy the gangrenous focus was found to be in the superior lobe.

ROUTIER operated upon a patient for localized empyema, resecting about ten centimeters of one rib. The pleura was stripped up, and through it a transpleural examination was made, but no information was gained. A small incision was made into the pleura and, as no focus of pus was found, the incision was prolonged and the surface of the lung inspected. Upon a line which seemed to mark the interlobular fissure, a needle was thrust in and drew pus. This was then opened and about a quart of pus evacuated. The patient recovered.

Routier described a kidney which he had removed on account of repeated unilateral hematuria. At first examination, the kidney appeared absolutely normal, but at the apex of one of the calices there was a small ulceration, which microscopical examination showed to be tubercular, and which had eroded a minute arterial branch.

Vienna.

RECOVERY FROM OSTEOMALACIA—A NEW STETHOSCOPE MADE ON THE PRINCIPLE OF THE DRUM—RELATIVE VALUE OF IODOTHYRIN AND TABLETS MADE FROM THE THYROID GLAND.

LATZKO presented before the Vienna Medical Club, February 10th, a woman who, in the sixth month of pregnancy, exhibited the symptoms of osteomalacia. She was treated with phosphorus, without effect, and it was finally deemed necessary to produce miscarriage. After labor, the bones again became solid, but the pelvic diameters were decreased to such an extent that it will be impossible for her to be delivered of a full-term child except by Cæsarian section.

At the session of the Imperio-Royal Society of Physicians, held February 19th, **BASCH** exhibited a stethoscope designed by himself and constructed on the principle of a Marruy's drum. The diaphragm is a thin sheet of rubber, which is protected by a rubber cloth. The instrument is superior to the phonendoscope. The sounds are not only increased, while their character is in no wise altered, but the analysis of the various acoustic phenomena is simplified. With this instrument the intestinal sounds and motions may be readily followed. It is also well adapted for the sounds of the fetal heart.

SCHIFF described experiments he had made to determine the quantitative value of iodothyrin and tablets made from the thyroid gland. It has been established that iodothyrin nas qualitatively the same effect as the thyroid tablets, but, as the result of the tests made upon four patients with three separate packages of iodothyrin and one of thyroid tablets, Schiff concludes that there is no quantitative equivalence between iodothyrin and the gland substance. Either all of the active principles of the gland do not unite with iodin, or else the iodin preparations lose their power in the course of time.

It was also brought out that different packages of iodothyrin are different in therapeutic force, so that the substitution of this new drug for the thyroid tablets is not recommended.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting held February 19, 1897.

A. B. JUDSON, M.D., Chairman.

SAMUEL KETCH, M.D., read the paper of the evening, entitled;

"REMARKS ON THE ORTHOPEDIC TREATMENT OF SPASTIC PARALYSIS IN CHILDREN."

[See page 385.]

DISCUSSION.

DR. FREDERICK PETERSON said that until he had heard the paper, he had known little about the orthopedic measures that are taken for the relief of these conditions. He asked if much can be done for the relief of spastic conditions in adults by means of tenotomies and apparatus. He took exception to the use by orthopedists of the term "irritability" in connection with these conditions, and did not think that the exaggerated reflexes which are present could be looked upon as "irritability." Exaggeration is due to the fact that inhibition from the cortex has been cut off—there is no irritability of the spinal cord. He thought this condition might be obviated by the use of the faradic current, which he considered preferable to the galvanic. A great deal of benefit will result from pedagogy, or education of the muscles by efforts of the will. Results of considerable benefit have been obtained from active instead of passive movements; as, for example, using the typewriter or playing the piano in the case of a paralyzed hand.

DR. WILLIAM LESZYNSKY said that in his experience no benefit whatever has been obtained from the use of electricity in these cases, but that much improvement resulted from efforts of the will and persistent manipulation of the limb. For instance, in a child with paralyzed limbs, the efforts made to walk are sometimes sufficient to restore the function of the muscles. In some of these cases of cerebral palsy, of course, but little can be done. It seemed to him that most of these cases are seen among the poorer classes. The better class do not allow their children to go so long without treatment, and the disease is not allowed to produce such marked deformities.

DR. REGINALD SAYRE said that to prevent these deformities treatment would have to be directed to removal of the lesion in the cord, which was a very difficult thing to do. He had seen many of these cases in the higher walks of life, and had found them just as intractable as those occurring among the poor.

He confirmed all the points which Dr. Ketch had brought up in the paper in regard to the results obtained from myotomies and tenotomies and the use of apparatus, but did not agree with him as to the employment of faradism.

DR. V. P. GIBNEY asked Dr. Leszynsky how he thought the deformities of spastic paralysis could be prevented.

DR. LESZYNSKY replied that patients of the well-to-do class do not get into such a bad condition as do those among the poor, because they seek treatment at an earlier stage. He thought that if a deformity had existed for years, there would be changes in the bone or joint, and believed he was right in considering such deformities difficult to rectify.

DR. H. L. TAYLOR asked the author to make more clear the indications for treatment in the different stages of these paralyses. He thought this class of cases owe a debt of gratitude to Dr. Bradford of Boston and to Dr. Gibney of this city, because of the benefit which has been derived from the combined use of braces and tenotomies as practised by them. In most of these cases there is a condition of contracture which is not easy to control by braces; *i.e.*, the deformity will return when the brace is removed. Tenotomy not only makes it possible to retain the foot in position, but has a decided effect upon the spasm. The tendon is cut for the specific purpose of relieving the spasm, and this point has been made clear by the surgeons mentioned. He thought the author had not sufficiently emphasized this fact in his paper. Another point is the very marked mental improvement which follows this mode of treatment. One of his cases was a little girl of six, who was very hard to manage, and who had what her mother called "tantrums." She now goes to a kindergarten, and has had no more "tantrums" since the tenotomy. The speaker said he would treat adults suffering from spastic paralysis in the same manner as he would treat children.

DR. H. W. BERG thought that almost all of these cases of spastic paralysis require a diagnosis as to their causation before any mode of treatment can be decided upon. Many of these cases accompany congenital idiocy, and in these pedagogy of the muscles will most aptly apply. The sense of sight should be developed by bright colors, that of hearing by the use of bells; at the same time the muscles should be developed to produce motor functions by making the child go through certain motions a given number of times, and repeat this until he learns how to do it. Good results can be obtained in this way after years of patient toil. Another class of cases results from meningeal hemorrhage during birth or at an early period of life, which destroys the motor area in the cortex, and results in degeneration of the cord. In such cases, education of the muscles is love's labor lost. These are the cases that do best under tenotomy. After a large experience in treating these cases with electricity, he was rather in favor of galvanism.

DR. N. M. SHAFFER said that a large number of these cases came under his observation both in hospital and private practice, and he had found that after a time the contraction becomes a contracture which is absolutely rigid, and yet, as time goes on, a radical change for the better will take place without any operative measures whatever. There is also improvement in the mental condition. He believed that this was due to the changes which take place in the body every seven years, and for this reason he often waited two or three years before operating. He ordered passive exercise to be kept up half an honr or an hour each day, and, so long as approximately normal movements can be gotten, did not think tenotomy necessary. Results obtained in this way are better than when tenotomy is done in the spastic stage. He had seen an elongated tendo-Achilles follow tenotomy done in the spastic stage, and this caused disability as great or greater than that which existed before the operation. It is also important that an apparatus be worn after tenotomy, in order to retain the limb in proper position.

DR. PETERSON remarked, in regard to improvement in the normal condition which Dr. Shaffer said often occurred when a radical change took place in these cases, that he thought this was merely a coincidence. In referring to the connection between these palsies and idiocy, Dr. Berg had spoken as if the paralysis was due to idiocy. The different degrees of idiocy and palsy, as well as epilepsy, are symptoms of cerebral injury received during parturition or within the first two or three years of life. Idiocy is a symptom which is found in fully fifty per cent. of all cases of spastic paralysis in children. Education of the muscles applies to all cases whether idiocy is present or not, and improvement in the mental condition often results from certain forms of pedagogy of the muscles. In regard to the use of electricity, he said that he did not see any advantage to be obtained from galvanism, and it often irritates the delicate skin of a child. The little patients soon become accustomed to faradism and rather like it.

DR. SHAFFER said that he scarcely thought the changes he had referred to are tissue changes. In one of his cases there was a change in the direction of the gastrocnemius, and he thought this might be due to the pathological condition instead of a change in the muscle tissue.

DR. BERG asked Dr. Peterson if he understood him to say that he considered every one of these cases as being due to meningeal hemorrhage. In some of these cases, was there not simply a lack of development of the motor centers or motor tracts? If so, he thought the treatment of the latter cases should differ materially from that employed in those cases where the paralysis is due to cerebral hemorrhage.

DR. PETERSON said that spastic paralysis, in a large majority of cases is due to meningeal hemorrhage, and that there are few cases where deficient development of the brain is found *post-mortem*. Atrophy, sclerosis, and cysts, are found in idiots.

DR. KETCH, in closing, said that his remarks were purely clinical, and that he had purposely left out anything that referred to the etiology of the condition. Dr. Peterson had objected to his use of the word "irritability." As most of the cases exhibit a general condition of irritability, described as "tantrums" by Dr. Taylor, he thought the term well applied. He had been asked to make clear the indication for tenotomy. A great degree of spasm would be to him an indication for the non-performance of tenotomy at that time. He believed with Dr. Shaffer that we should wait until the stage of contracture before operating. Each case should be studied individually, and the treatment governed by the amount of spasm and irritability. He could give no satisfactory reason for the mental improvement which takes place in some of these cases, but thought it might be the natural result of time.

SPECIMEN SHOWING "SECONDARY POTT'S DISEASE WITH COMPRESSION OF THE CAUDA EQUINA, FOLLOWING EMPYEMA."

DR. GEORGE T. ELLIOTT presented a specimen from a man, twenty-eight years of age, who had tubercular involvement of both lungs and purulent exudation into the right pleural cavity. Slight lumbar kyphosis appeared later, with partial motor paralysis of the lower extremities and pain and knee-jerks which varied with the position of the patient. While the patient lay on the right side, the pain ceased and the knee-jerks appeared, the latter disappearing when he lay on the left side or back. At the autopsy the right pleural cavity was found filled with pus. An extradural sinus extended from the tenth dorsal vertebra, where it communicated with the right pleural cavity, to the second lumbar vertebra. The tenth vertebra was carious and the fourth and fifth lumbar softened, with a small abscess cavity separated from the cauda equina by an area of pachymeningitis externa caseosa. The ventral surface of the dura was intact. The extradural sinus rested upon this caseous mass and did not mix its contents with those of the extrapachymeningitic abscess cavity. There was no microscopic degeneration of the cord. The points of interest are as follows: (1) Entrance of pus from pleural cavity into vertebral canal, the usual order reversed. (2) Dual secondary involvement of vertebral column. (3) Compression symptoms varying as the patient changed his position, and with a varying quantity of pus in the epidural canal which communicated with the pleural cavity containing pus.

The patient had had lung trouble before any symptoms of vertebral caries appeared. The speaker could not say whether or not any attempt had been made during life to evacuate the pus in the pleural cavity.

REVIEWS.

THE PRACTICE OF MEDICINE. By HORATIO C. WOOD, A.M., M.D., LL.D. (Yale), Professor of Therapeutics and Clinical Professor of Nervous Diseases in the University of Pennsylvania, etc., and REGINALD H. FITZ, A.M., M.D., Hersey Professor of the Theory and Practice of Physic in Harvard University, etc. Philadelphia: J. B. Lippincott Co., 1897.

THE authors state in their preface that this work is the "outcome of an attempt to view the practice of medicine simultaneously from the pathologic and therapeutic points of view," and there are few who, having read the book, will not admit that the attempt has been successful. Wood's eminence, his preëminence, in fact, as a therapeutic teacher, enables him to speak authoritatively on the treatment of disease, and all the therapeutics of the book have been written by him. Fitz's reputation as a pathologist renders the reading of the morbid anatomy of each chapter clear, and it is evident that, concerning most of the conditions, he has seen many examples.

The book begins with a full chapter on the diseases of the blood and of the ductless glands. The thyroid extract is heartily commended in cases of goiter and myxedema, but no reference is made to the recent discovery of the presence of iodin in the thyroid gland, which probably accounts for the benefits derived from this variety of animal extract in the proper cases. The locomotor and constitutional diseases, and the infectious diseases, are next discussed. The section on tuberculosis is especially well arranged and splendidly treated. The authors do not specifically recommend the injection of tuberculin, though they state that it is viewed with favor by some writers. The antitoxin treatment of diphtheria is urged "whenever the clinical features of the case warrant the diagnosis of diphtheria." The writers properly point out the difficulties of securing perfect results when the infection is a mixed one. No mention is made of the use of the antistreptococcus serum in cases of pyemia aud septicemia.

A chapter on "Animal Parasites," very complete and instructive, is followed by one on "Acute and Chronic Poisoning," which is a valuable element in the book. The "Diseases of the Nervous System" occupy the next 240 pages. In the treatment of this subject Wood has left nothing to be desired, though it is a little surprising that he has not referred to Quinche's lumbar puncture as a diagnostic measure.

The succeeding sections are devoted to the diseases of the circulatory apparatus, of the digestive apparatus, and of the peritoneum. The Charcot-Leyden crystals of asthma are spoken of as Charcot crystals. Under the diseases of the lungs tuberculosis is not described, being fully treated in the chapter on infectious diseases. Although the technic of staining and preparing microörganisms belongs, perhaps, more properly to works on diagnosis, a description of them would not be out of place in a book on practice so voluminous as this.

One turns naturally with some eagerness to the discussion of appendicitis in this work, since Fitz was the originator of the term and the first one to describe fully the morbid anatomy of the process. His original observations still stand as classical descriptions of the various forms of the process. The authors recommend surgical reatment of appendicitis when the symptoms point to a perforation; when sixty hours of treatment shows no abatement of the symptoms; and "when a sudden increase in the local and general symptoms points toward the occurrence of perforation or the formation of pus." Operation in the interval of attacks is recommended, Wood preferring to have the appendix removed directly after the recovery of a second attack. Fitz advises removal in cases in which recurrences are frequent or the tendency to relapse is such as to produce a state of semi-invalidism.

The last section of the book is devoted to the diseases of the kidneys, with a full consideration of abnormalities of the urine. A formulary of twenty-eight prescriptions and a number of temperature charts are appended to the work. The index is quite complete.

On the whole, this latest addition may be cordially recommended as a text-book of medicine, it being a recent, full, and authentic exposition of the subject. The standing of its authors can be but enhanced by this publication.

The only objection to be made to the work of the publisher lies in the inferior quality of the paper.

THE EYE AND ITS CARE. By FRANK ALLPORT, M.D., Professor of Clinical Ophthalmology and Otology in the Minnesota State University, etc. Philadelphia: J. B. Lippincott Co. 1896.

This little volume of 172 pages is devoted to a consideration of the anatomy, physiology, and hygiene of the eye, presented in an elementary, popular style. No attempt at originality is claimed. The book is well printed, fully illustrated and attractively bound. The non-medical student who thirsts for a little knowledge of the eye will find this work of value.

THE PRINCIPLES OF THEORETICAL CHEMISTRY, WITH SPECIAL REFERENCE TO THE CONSTITUTION OF CHEMICAL COMPOUNDS. By IRA REMSEN, Professor of Chemistry in the Johns Hopkins University. Fifth edition. Philadelphia and New York: Lea Brothers & Co. Pp. X to 326. 1897.

AS the author states in the preface, this new edition has been prepared on the lines of the preceding ones, his object being "to help students to get clear ideas in regard to the foundation of chemistry." This little work states in brief all that is known of the modern theories of chemistry, with a sketch of their development. It especially points out the value of the work of Lavoisier in putting us in a position to investigate the laws of chemical change, making chemistry more of an exact science than it had previously been.

The molecular theory is then fully discussed, and the value of the periodic law, as a means of classification of the elements, is pointed out. The author devotes much space to the constitution of chemical compounds, and the physical methods of their determination; a passing glance being had of stereo-chemistry, and the study of chemical affinity.

On the whole, this little book is worthy of attention by the student of theoretical chemistry and of chemical problems.

ANNOUNCEMENTS.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

THE American Climatological Association will hold its fourteenth annual meeting in Washington, D. C., May 4, 5, and 6, 1897.

The sessions will be held daily from 10 A.M. until 1 P.M. in the Columbian University Building.

The general sessions of the Congress will be from 2 until 5 P.M.

The annual dinner of the Association will be held on the evening of May 4th, at the Hotel Normandie.

President, Dr. E. Fletcher Ingals, Chicago.

Secretary and Treasurer, Dr. Guy Hinsdale, Philadelphia.

PRELIMINARY PROGRAM:

"President's address," E. Fletcher Ingals, M.D.

PAPERS.

"Choice of a Summer Residence." F. I. Knight, M.D.

"Mountain Fever." Thomas Darlington, Jr., M.D.

"Renal Disease as Affected by Climate." I. N. Danforth, M.D.

"Climate or Environment as a Factor in the Repair of Neurasthenia and Melancholia." J. Madison Taylor, M.D.

"Nervous Diseases Affected by Climate." Sanger Brown, M.D.

"The Comparative Merits of Resorts in Colorado, New Mexico, and Arizona." S. E. Solly, M.D.

Paper by R. G. Curtin, M.D.

"A Brief Consideration of Some Points in the Management of Consumption." Submitted for discussion. R. H. Babcock, M.D.

"Cases of Pulmonary Tuberculosis with Recovery." John H. Musser, M.D.

"The Clinical Value of the Culture Products of the Bacillus Tuberculosis in Tubercular Affections." Karl von Ruck, M.D.

"Terebinthinates as Remedial Agents." J. B. Walker, M.D.

"Aero- and Hydrotherapeutics in the Prevention and Treatment of Pulmonary Tuberculosis." S. A. Knopf, M.D.

"Infrequency of Pneumonia on the Atlantic coast of Florida." Frank Fremont Smith, M.D.

"Remarks on the Treatment of Tuberculosis by the Antitubercle Serum." Guy Hinsdale, M.D.

"Some Personal Observations upon the Effects of Changes of Climate upon the Health of Men and Animals," R. C. Newton, M.D.

"Dangers of Tubercular Infection and Their Partial Arrest by Climatic Influences." C. F. Gardner, M.D.

"Does the Institution Treatment Promise the More Certain Cure in Pulmonary Tuberculosis?" C. P. Ambler, M.D.

"The Treatment of Gout by Natural Mineral Waters." C. C. Ransom, M.D.

"Report on Mineral Springs." A. C. Peale, M.D.

"The Treatment of Hæmoptysis with the Salicylates." Thomas J. Mays, M.D.

Papers by Thomas D. Coleman, M.D.; C. F. McGahan, M.D.; H. L. Elsner, M.D., and others.

Members should purchase a ticket to Washington with a certificate of purchase. Presentation of this, countersigned by the agent at the Congress, will entitle members to return at one-third the regular fare.

The headquarters of the Association will be at the Hotel Normandie, which has made special rates of from $3 to $3.50 per day.

Members intending to be present at the dinner will advise the Secretary as early as convenient, as it will take place on the evening of the first day.

Abstracts of papers should be forwarded to the Secretary in advance, and all manuscripts given to him as soon as read.

NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING AND LICENSING BOARDS.

President, Wm. W. Potter, M.D., N. Y. Secretary-Treasurer, A. Walter Suiter, M.D., Herkimer, N. Y.

The seventh annual meeting of this Conferation will be held in the small banquet hall of the Hotel Walton, at Philadelphia, Monday, May 31, 1897, at 10 o'clock, A.M. The following program has been arranged:

1. Address of welcome by A. H. Hulshizer, M.D., of Pennsylvania State Board of Medical Examiners.
2. Response by Vice-President Reed.
3. Report of the Committee on Minimum Standard of Requirements.
4. Discussion and action thereon.
5. Report of the Secretary and Treasurer.
6. Annual address of the President.
7. "Some Practical Experience with, and Results of, the Medical Law of Pennsylvania." Wm. S. Foster, M.D., Pittsburg.
8. "The Need for Exact Information as to the Equipment, Methods, and Requirements of our Medical Schools." J. H. McCormack, M.D., Bowling Green, Ky.
9. Address by Professor J. W. Holland, M.D., Dean Jefferson Medical College, Philadelphia.

The object of the Confederation is to consider questions pertaining to State control in medicine, and to compare methods in vogue in the several States; the collection and dissemination of information relating to medical education, and to consider propositions that have for their purpose advancement of the standards in the United States. A cordial invitation is extended to all members and ex-members of State medical examining boards, and to physicians, sanitarians, and educators who are friendly to the objects named, to attend the meeting and participate in its proceedings.

MEETINGS OF NATIONAL MEDICAL SOCIETIES, 1897.

NAME OF SOCIETY.	PLACE.	TIME.	SECRETARY.	RESIDENCE.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, APRIL 3, 1897. NO. 14.

ORIGINAL ARTICLES.

THE USE OF MODIFIED MILK IN HEALTH AND DISEASE.[1]

BY T. M. ROTCH, M.D.,
OF BOSTON;
PROFESSOR OF DISEASES OF CHILDREN, HARVARD UNIVERSITY.

SUCH great advances have been made in the use of milk as a food during the last few years, and so much interest has arisen among the members of the medical profession regarding this subject, that this would seem an appropriate time to discuss, at least provisionally, the position which milk-feeding holds at the present day. I should like to at once impress upon you as medical scientists, as practical and intelligent physicians, whether you are undertaking to provide for the nutrition of the earlier periods of life, or for the various phases of malassimilation, malnutrition, or gastro-enteric disturbance, in the old as well as in the young, that we are but in the beginning of our knowledge of a subject which, broad as it has appeared in the past, has tripled and quadrupled within a decade, and now opens up long vistas for future thought and research. We are not in a position to-day to say exactly what are the best modifications of milk to be used in all the manifold instances in which some modification is evidently indicated. We have learned that to modify milk is a wise and valuable adjunct to our treatment, and, in certain instances, what combinations of the constituents of the milk are best for the individual case.

From the milk laboratories of New York, Buffalo, Providence, St. Louis, Montreal, Chicago, Philadelphia, Baltimore, and Boston, we have already had thousands of people of all ages fed. From these laboratories have emanated thousands of prescriptions, written by over 2000 physicians. I have prescribed for a large number of individuals, but I do not feel, excepting in a limited class of cases, that I can tell you what should be prescribed for a special individual. When we consider that hundreds of physicians have been prescribing from these laboratories who have never spent a day, or even an hour, in really learning how or when the various combinations of the constituents of the milk should be given, is it any wonder that we should hear of failures in the individual treatment?

Looking at the subject as a whole, however, what stronger evidence can we have of the value of the principle that different individuals, both in health and disease, require different combinations of the constituents of the milk to suit their especial case than that, with all the ignorance of the prescriber working against the prescription, still, the result is that in a vast majority of instances the patients have done well? The position which it seems fair for us to take is that the principle of the modification of milk is scientific, is practical, is right, and that in the milk laboratory we have one more instrument of precision to aid us in our work, and that in all probability the failures are not to be attributed to the principle and the instrument, but to us, who, acknowledging the principle as a whole, and using the instrument, are as yet ignorant of the details which make up that principle and do not do the instrument justice.

What have we accomplished in our investigations of this subject? Where do we stand? In what direction should we work in the future? There is no doubt, in my mind, that the true and only way of approaching the problem of feeding is by turning the searchlight of scientific experimental investigation upon every one of the old ideas which time and tradition have imbued us with, and see whether these ideas and traditions will stand the test. A wise and complete iconoclasm is surely what we need to prepare a firm basis on which to build up a more rational system of feeding than has ever been dreamed of in the past. Dogmas, even though supported by the names of some of our most revered teachers, must be put aside if they do not stand before our modern methods of research. It will not satisfy us, because our predecessors said so, to claim that cereals in the milk lessen the size of the curd, if it has been proved in the chemical laboratory that they do not. It will not do, because supposed authorities have said that separating milk into its component parts destroys the emulsion, to accept this fanciful statement when, by means of photography, it has been proved that it does not. It will not satisfy us that because the expert chemist has told us that the proteids in human milk average 1 to 1.50 per cent. to therefore insist upon feeding infants on 1 per cent. of proteids when clinical evidence, combined with chemical analysis, teaches us undoubtedly that what is true and good for the average may be false and productive of harm to the individual, and that the secret to the correct management of the proteids is the new principle that variety, and not uniformity, produces the best results.

---

[1] Read before the New York Academy of Medicine, February 18, 1897.

In contradistinction to those who claim that a given percentage should be given at a given age, we can show, by means of analyses made in the different months of lactation, and in different individuals, as seen in the accompanying table, representing a number of good human milks from mothers whose infants were thriving, that we must study the proteid digestion of the individual infant and discover the idiosyncrasy of the especial stomach.

Human Breast-Milk Analyses.

(Mothers healthy and infants all digesting well and gaining in weight.)
[Harrington.]

Constituents.	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII.	XIII.	XIV.
Fat	5.16	4.88	4.84	4.37	4.11	3.82	3.80	3.76	3.30	3.16	2.96	2.36	2.09	2.02
Sugar	5.68	6.20	6.10	6.30	5.90	5.70	6.15	6.95	7.30	7.20	5.78	7.10	6.70	6.55
Proteids	4.14	3.71	4.17	3.27	3.71	1.08	3.53	2.04	3.07	1.65	1.91	2.20	1.38	2.12
Ash	0.17	0.19	0.19	0.16	0.21	0.20	0.20	0.14	0.12	0.21	0.12	0.16	0.15	0.15
Total solids	15.15	14.98	15.30	14.10	13.93	10.80	13.68	12.89	13.79	12.22	10.77	11.82	10.32	10.84
Water	84.85	85.02	84.70	85.90	86.07	89.20	86.32	87.11	86.21	87.78	89.23	88.18	89.68	89.16
	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00

On examining these analyses you will observe that the percentage of the proteids varies greatly, and in only one case approaches one per cent. In a number of these cases where the infant which was thriving on one of these milks was changed to another, it ceased to do well, and suffered from acute indigestion. This at once opens up the question of the various artificial foods, and whether it is worth while to use them. There are only certain food elements which can be made use of, no matter what food as a whole is demanded. The artificial foods, if well made, should be unvarying. We all know that they must vary. If they vary, we must at once give up any idea of feeding with exact percentages of the different constituents of the food. Even if they do not vary, do we know enough about the exact percentages of these constituents to calculate how, in the completed whole, as mixed for the patient, we can give just such percentages as we deem best for the individual? That is, the *elements* of the food may be there, but the *combination* we do not get in any near approach to exactness.

Our investigations teach us that variety and comparatively exact combinations constitute the true principle of successful feeding and a resulting perfect nutrition. Is it not better to entirely put aside an uncertain conglomeration of the constituents of the food represented by these artificial foods and substitute in its place an exact method of combining these same constituents? Is not this the only intelligent and indeed practical method of dealing with such a difficult question as malnutrition?

There is very little question, but that by the careful mathematical calculations which are made by means of the Walker-Gordon laboratory tables, that at least more exact combinations of especial percentages of the constituents of food can be made than ever before. What is of equal importance also is that by these tables we enunciate the great principle in feeding, namely, that *variety* to suit the individual digestion is required and can be obtained by a simple prescription of a few figures; also, that an almost unlimited number of different combinations of the constituents of food can be made by the physician in as many minutes, and by the laboratory in as short a time, according to the number of clerks employed. I use the word "laboratory" simply to cover the idea of the principle involved. The changes in the percentages may be made by home modification; not so well as by the laboratory methods. Still, there are those who like to argue the question of their own peculiar way of arriving at correct results in home modification, disregarding the fact that to obtain an exact combination of the constituents of the food needs skilful mechanical training, as well as a correct calculation of figures, and that the personal equation of mother and nurse at home is often a serious drawback to the successful mixing of the food, for this mixing cannot be, in the vast majority of cases, so well done by mother and nurse as by the trained clerk in the laboratory. There are many other obstacles to the success of home modification which may arise. For instance, on four successive days here in New York, at the same reputable dairy, I had the request made to give me for purposes of home modification, for a sick infant, an unvarying cream. This cream, obtained from an honest, conservative dealer, I had tested each day, with the result of finding a variation in the percentage of fat from 10.13 to 28.34, which, of course, would at once preclude any chance of obtaining an unvarying percentage of fat in the mixture as given to the patient.

I have spoken of the uncertainty which arises when the physician endeavors to carry out an exact modification at home from the varying percentages of purchased dairy cream. But I have also found the "top milk process" (as it is called) also very uncertain. Milk set for the raising of cream by gravity, whether in an open pan, a jar, or a Cooley can, will vary with differences in the atmosphere or in the medium in which it is set. With great attention, though, the night or evening milk can be creamed in ten hours, with some degree of regularity in percentage. But it needs attention every fifteen minutes during this time. Open pan and jar setting is uncertain in its results, so that, unless debarred from access to a scientific laboratory, the physician cannot hope to obtain any great degree of exactness by home modification. The percentages of the sugar and the proteids will also vary from day to day in about the same way, though to a less degree than does the fat. A predetermination of the milk each day before modification by the usual dry process is indispensable to exactness in modification. This is expensive and tedious.

I wish also to speak briefly about the important question of employing for all infant feeding a safe milk. A safe milk is hard to obtain from the farm or dairy, and is especially hard to obtain in the private stable. A safe milk is a matter of the producers' conscientious work. The veterinarian must be constant in attendance to guard against such a common danger as tuberculosis. But perhaps the danger of infection in milk from this disease is very slight compared with danger of infection from other sources. Typhoid fever, diphtheria, and scarlet fever are easily transmitted by rinsing water, by the milker's hands and clothes, and by other common sources of dairy infection. These are common sources of danger, and yet perhaps not so dangerous as more subtle sources which lie outside of the observation of the physician who has charge of the modification. The rôle which the streptococcus pyogenes plays in infant pathology is very uncertain, and its virulence varies in any given instance. Yet it is beginning to be believed that this so-called non-pathogenic coccus becomes highly pathogenic in certain company, and that milk containing these cocci, which are quite commonly present in average dairy milk, becomes at times especially dangerous to the consumer. The experiments of Nivens in 160 cases, of Kruger (1890), of Guillebeau in seventy cases, of Karluiske, Escherich, Longard, Adamitz, Stokes, Bullock, Tonarelli, Ceveiuville, Taval, and especially Booker, all connect severe diarrheas in infancy and acute gastroenteritis with the presence of this organism.

Of especial interest in this connection are the observations of Stokes and Clement on a herd of seventy cows who were infected by the hands of a strange milker, who had had one of his fingers infected when working on a large dairy farm in York, Pa. A complete autopsy made on one of these cows showed that there was no general infection, but that the septic process was limited to a somewhat purulent inflammation of the milk ducts. Dr. Stokes also traced the source of an epidemic of diarrhea which broke out in a school of seventy girls, to milk from cows infected with this local sepsis. These opinions are to be taken for what they are worth in the individual mind of the physician, but the fact cannot be ignored that in nearly all farm, dairy, or private stables, the milk produced very commonly contains large numbers of these organisms. The fecal matter from the cow is a constant source of danger, and is present in nearly all the milk of commerce, while a direct pus contamination often occurs.

Of course, with great care and perfect supervision home modification may be done with more or less exactness and safety, but this entails a large amount of personal responsibility, which is guaranteed to the patient when the infant is fed from the laboratory by prescription, both as to the primal milk employed and as to the accuracy with which the prescription is filled.

In like manner there are physicians who, in their cry of *cheap* food for the people, do more toward injuring the cause of *proper* food for the people than any class that I know of. According to my own experience, it is the people of moderate means, and even the poor, who most appreciate the advantages of feeding by exact methods, and that it is the rich, aided and abetted by physicians ignorant of the rudimentary laws of physiology and development, who are continually preaching economy in regard to the most important factor in the problem of perfecting the human race through its nutrition; and it is this same class who uphold far greater expense in other branches of medicine. A good thing costs and should be paid for. Money is not ill-spent in developing in the best way those who must make and use that money in the future. The importance of this self-evident truth should be impressed on the people by physicians. Antitoxin is not withheld from the man of moderate means because it is expensive; its employment is the best for the patient, and he gets it, whatever his means may be. The infant, with its low vitality and its high mortality rate, should have the best means for reversing these rates, in the midst of its struggle for life. Let not the millions spent in charity be given entirely to the treatment of disease. Let some of it go to the cause of prophylaxis in the early periods of development, and to the proper management of the nutrition which, in the young, will do more to withstand disease, when it comes, than pounds and quarts of drugs.

Although I cannot as yet give you exact rules for the modification of milk in health and disease, I cannot help feeling that, from the large number of cases which I have treated in this way, certain impressions which I have derived from watching carefully the results of this treatment may be of some use to those of you who are working in this field of medicine. I shall not discuss such a side-issue as the use of cereals in a food for the early months of life, as it is the food which nature provides, containing certain elements, and no others—fat, sugar, proteids, salts, and water, which we are at present considering. In regard to the proteids, however, I would draw your attention to the fact that careful experiments have been carried out which show that, no matter what cereal or artificial food is added to milk, the size or density of the curd is not diminished. I would also state that in both health and disease, both in the infant, child, or adult, with the exception of a few especial cases, I have personally found that I am more successful in managing a difficult proteid digestion, not by predigesting the proteids, but by reducing them first to a minimum and then gradually, as the proteid digestion becomes stronger from not being overtaxed, increasing the proteid percentage until the amount necessary for nutrition is attained. Thus, beginning with the proteids 0.25 for all ages, whether infant, child, or adult, I increase up to 1 to 1.50 for infants, 2 to 3 for children, and 3 to 4 for adults.

It may, perhaps, be of some significance also to state that in making a careful analysis of 164 fully recorded cases treated at the Boston Walker-Gordon Laboratory, I have found a decided reduction in the percentages employed, amounting to at least fifteen per cent. during the last two years, in comparison with the high percentages used in the previous two years, and that during the same two years here in New York the same reduction has been found in the prescriptions sent to the laboratory by the New York physicians. That is, we are learning that low percentages, if carefully adjusted, produce better results than beginning with high ones. I have also found, somewhat to my surprise, that a critical review of my own prescriptions shows that my tendency has been to increase the proteid percentage much more slowly than in former years, and that I arrive at the percentage of 4, which is that of cow's milk, rather after the twelfth month than at or before that age of the infant. In private practice also the rule has been that in summer the most successful treatment of diarrheal cases has been with low percentages of all the elements of the milk, the average percentages being: Fat, 1.50 to 2.50; sugar, 4.50 to 5.50; proteids, 0.25 to 0.67.

I would also say that in modifying milk and carefully using the many different combinations at our command my experience does not accord (except in a very limited number of cases, and those arising probably from my own ignorance of the instrument I was using) with the experience of those who believe that certain individuals cannot take milk, or that milk is contraindicated in certain diseases. All foods contain practically the same constituents, and milk, or milk mixed with starch, comprises all these constituents. The individual does not reject milk, or suffer from malnutrition caused by the administration of milk. Milk is not contraindicated in an especial disease; on the contrary, it is some element, or constituent, or combination of the constituents making up the milk, wherein the fault lies. We might just as well at once, and better, too, because we can do it more exactly and more simply, find out by changing our modification whether it is the fat, or sugar, or proteids, or total solids, or starch digestion which is weak or diseased, or which, as a culture ground, will encourage bacterial growths in the individual. We can then remedy the trouble by not overtaxing the especial function until it has had time to recover its normal power. The great mistake which those make who experiment with foods is that they look upon the different foods and their action and effects in health and disease as a whole, and not at the details which make up this whole. Milk, as a whole, is a mild and simple dinner made up of the same food-constituents as are placed on our tables, excepting that in it we have the starch predigested into sugar. One individual can thrive best on an excess of vegetable food, another on fats, another on meat, and this idiosyncrasy of the individual in early life and in disease in later life can be met by simply modifying these food-constituents in the milk.

While studying the question of whether separating the fat from milk, and then recombining it in various percentages, might possibly produce any great change, such as a disturbed emulsion, and thus injure the food in some way, I had photographs taken of (1) cow's milk, (2) of cow's milk separated and recombined, (3) of human milk, and (4) of a modified milk of the same percentages as the human milk.

There does not seem to be such a perceptible difference between the resulting emulsions in these specimens as to make one believe that any difference exists between unseparated milk and the same milk separated and again combined.

In a fairly large experience derived from the care of infants who have been fed from the first days of life among people who have had sufficient means to give their children the best hygienic surroundings, I can state that I have never yet seen an infant who was carefully fed on milk during the first ten or twelve months of its life, by carefully changing the percentages of the milk constituents, and on nothing else, not enter upon its second year with firm flesh and an average development. I have found the teeth to be sound, and to come at the usual age. I have found the functions of sitting, walking, and standing, and the amylolytic function all appear and develop normally. I have followed these children into their third, fourth, and fifth years, and have found them strong, ruddy, with good bones and teeth, and with digestions which permit them to be fed on a general mixed diet of all the food elements.

Where I have been especially struck with the value of the idea that we should think, write, and speak in percentages representing the constituents of food, and not prescribe foods as a whole, is in the feeding of premature infants. Here we have a stage of development which peculiarly illustrates the principles of milk modification. In this early period of development, not only are the lungs and heart immature and in need of a carefully modified air, but the gastro-enteric tract is also undeveloped in its size and functions; it needs smaller quantities of food and shorter intervals of feeding than the stage of development met with at birth. Its functions are essentially weak, are not ready to be used, and if used, as they must be to support life, they are easily overtaxed, as I have proved over and over again. If we but recognize that while the fat digestion with its percentage of 3 to 4, the sugar digestion 6 to 7, the proteid digestion 1 to 1.50, are so well developed in the average infant at term, and so well provided for by human breast-milk with its percentages corresponding to what the digestive functions of this stage of development are ready to receive, we must realize, on the contrary, that the premature infant's digestive functions are in an earlier stage of development, and that at the seventh month of intra-uterine life the fat percentage, instead of being 3, as at the ninth month, may only be 1, the sugar digestion, instead of 7, may be only 3 or 4, and the proteid digestion, instead of 1 or 2, may be only 0.25 or 0.45,

These rules I have tested clinically, and they are significant as showing that nature, while providing the best food by means of the human breast for the stage of development met with at term, does not provide a suitable food for the stage of development met with in the seventh and eighth month of pregnancy. Also, that many a premature infant has died from being put to the breast of its own mother, for the human mamma has not been made to modify its milk constituents into low percentages, but from long ages of use and inheritance has been taught to modify in the higher percentages adapted to the tenth, eleventh, and twelfth, or rather first, second, and third months of life. In this class of cases, therefore, there seems to be no question that the careful modification of cow's milk by dealing with low percentages gives the premature infant a far better chance for life than does human breast-milk. Any one who has followed a premature infant from the day of birth, giving it up to the time of weaning nothing but carefully combined percentage feeding, seeing it digest and thrive first on 0.50 of fat, 4 of sugar, 0.25 of proteids; then on 1 of fat, 5 of sugar, 0.50 of proteids; then 1.50 of fat, 5.50 or 6 of sugar, and 0.75 of proteids; then on 3 of fat, 6.50 of sugar, 1 of proteids; then on 3.50 of fat, 6.50 of sugar, 1.50 of proteids; then on 4 of fat, 7 of sugar, and 2 of proteids in the sixth month, cannot help feeling that, at least, we are approaching the time when an exact system of dealing with nutrition is to be hoped for.

With equal satisfaction can we look upon the value of milk modification for purposes of weaning. Taking up the last percentages which I have just mentioned, fat 4, sugar 7, proteids 2, we now wish to replace at perhaps the tenth, eleventh, or twelfth month, in some cases later, this modified milk by unmodified cow's milk with its percentage of fat 4, sugar 4.50, and proteids 4. In no way can this be done so well and so satisfactorily as by slowly changing the percentages until they have approached each other so closely that the digestive functions of the infant cannot help being ready to receive unmodified cow's milk.

During the past three summers a large number of poor infants suffering from diarrheal diseases have been fed from the Boston Milk Laboratory on modified milk. Last summer having complete control of the fund which, chiefly through the generosity of Mr. N. S. Bartlett, has been donated for this purpose, I was enabled to have the administration of the milk kept under somewhat strict supervision. To accomplish this I only allowed it to be dispensed from three of the clinics where responsible physicians were in attendance. I also had a physician who thoroughly understood his work supervise all the cases which were treated. The results were most satisfactory, and in fact the universal opinion of all the many physicians in Boston who have watched and endorsed the principle of modification in the treatment of the summer diarrheas of infancy, is that it is unquestionably beneficial. Of the 115 gastro-enteric cases which were carefully analyzed while being treated with modified milk, 5 died, in 1 there was no improvement, and 109 recovered. Of those who recovered 23 did not have their modification changed but did well. Eighty-six had a number of changes made in their modifications and did well. The average age of the patients treated was 6.42 months. The milk in all cases was heated to 167° F. The average number of feedings was 7.5. The average amount at each feeding was 4.5 ounces. The average alkalinity was 6.3 per cent. The average percentages given were: fat, 2.6; sugar, 5.8, and proteids, 1.2.

What I hope in the future to accomplish is to have the diarrheal cases so differentiated that they will be fed and treated by a reduction of the especial constituent of the milk which appears to offer a culture ground for the development of especial flora in the intestines.

In conclusion I would impress upon you how important I have found it to be to always carry out strictly all the many details which are necessary if we wish to obtain satisfactory results in the feeding of cases of difficult digestion.

SERUM DIAGNOSIS OF TYPHOID FEVER, WITH REPORTS OF FIFTY-SEVEN CASES TESTED FOR THE REACTION BY EXAMINING SPECIMENS OF DRIED BLOOD.[1]

By JEROME B. THOMAS, Jr., M.D.,
OF BROOKLYN;
ASSISTANT BACTERIOLOGIST TO THE BROOKLYN HEALTH DEPARTMENT, ETC.

ABOUT two months ago, very soon after the appearance of an article by Dr. Wyatt Johnston of Montreal on the application of the serum diagnosis of typhoid fever to the requirements of public health laboratories, I began a practical test of his method at the suggestion of Dr. E. H. Wilson, chief of the Bacteriological Bureau of our own Health Department. The purpose of this paper is to make known the results of these investigations and weigh their practical and clinical significance.

The phenomenon which is commonly spoken of as the "Widal reaction" may be briefly described at the outset as follows: Add a certain proportion of blood serum from a patient suffering from well developed typhoid fever to a bouillon culture or watery emulsion of the typhoid bacillus, and in from thirty minutes to several hours flocculi or clumps will have formed throughout the mixture and fallen to the bottom as a granular sediment, leaving the overlying fluid more or less clear. A control culture of the typhoid bacillus treated in the same way with the blood of a non-typhoid, sick or well, will remain uniformly cloudy, with no sediment. If a drop of the former mixture be transferred to a cover-glass and examined microscopically the bacilli will be seen to gather into masses and become motionless, while the few that remain free gradually lose their motility. A drop of the latter mixture will be seen to contain very actively motile bacilli evenly distributed throughout the fluid, and this condition will be found to persist for hours, and even days, if the specimen be properly sealed to prevent evaporation. To the agent which causes this agglutination, and which seems to be identical neither with the bactericidal or the immunizing substances of the immune sera, Pfeiffer has given the name "paralysin," and Gruber "agglutinin."

Knowledge of changes in the form of bacteria due to the action of sera of immunized animals rests on R. Pfeiffer's original experiments on specific cholera immunity. The so-called "Pfeiffer reaction" may be described as follows: Inject a mixture of an emulsion of the vibrios (cholera, etc.) which are to be tested, with a minute quantity of the serum of a very highly immunized animal into the peritoneal cavity of a normal guinea-pig. If the reaction is positive, all the vibrios are converted into spherules or coccus-like bodies in an hour or less. According to Pfeiffer, the vibrio is then to be regarded as belonging to the same species as that by means of which the immunization of the animal was carried on. If, on the contrary, the reaction is negative, the vibrios are unaffected after remaining an hour or more in the guinea-pig's peritoneal cavity, and are then considered to be of a different species from those used for immunization. In this same connection Pfeiffer demonstrated that the blood serum of animals immunized against cholera protects other animals against otherwise fatal doses of the cholera culture. He also noted the agglutination of the vibrios when combined with the serum, as described above, and he showed that the serum may cause this clumping outside of the animal's body if first injected for awhile into the peritoneal cavity of a sound animal. He demonstrated the same fact with typhoid serum and cultures.

Issaeff and Ivanoff, working with the *vibrio Ivanoff*, have the credit of having first demonstrated the reaction in gross and without the direct or indirect aid of the living body. This vibrio grew abundantly in the serum of a normal guinea-pig with clouding of the mixture. In the serum of an immunized guinea-pig flocculi formed, and in a few hours fell to the bottom of the glass as a sediment, leaving the supernatant fluid clear.

---

[1] Read at the meeting of the King's County Medical Association, January 13, 1897.

Gruber and Durham[1] were the first to thoroughly describe the reaction and weigh its practical and theoretical value. They emphasized the reaction outside of the body of an animal (*in vitro*) and proposed its use instead of Pfeiffer's reaction to identify cholera and typhoid bacilli. Furthermore, Pfeiffer's reaction is regarded by them to be of a dual nature: (1) The weakening of the microbes before injection by direct action of the active serum. (2) The normal bactericidal influence of the guinea-pig's peritoneal fluid upon these weakened microbes. Very weak cultures treated with normal serum, and virulent cultures weakened by heat react in the same way on injection. They conclude, in this connection, that the reaction in vitro forms the essential part of Pfeiffer's reaction in so far as any specialized action is concerned, and that the use of the peritoneal fluid of a living animal obscures many of the points of difference which can be observed in the action of different sera. They demonstrated the phenomenon with cholera and many other vibrios, with several races of typhoid and colon bacilli, and also with the bacillus pyocyaneus, each being treated with its own or like serum—that is, a serum taken from an animal immunized with the same race that was being tested. They further prognosticated that the process occurs with all kinds of motile bacteria, and stated their belief in the probability that non-motile bacteria also will be found to react in a similar manner under the influence of their appropriate sera. In support of this, they mention typical reactions with colon bacilli, a majority of the individuals being devoid of the power of movement before the addition of the serum, and many of them unprovided with flagella; also, observations of "granular agglomerations" in hog-cholera bacilli (Metschnikoff), and in pneumococci (Washbourn), when grown in their own serum. They demonstrated that various chemical solutions, heat, foreign sera, tuberculin, etc., though they may influence the motility of the germs under observation, do not cause agglutination. In their experiments with typhoid serum, two kinds were used, with nineteen varieties of typhoid bacilli. All reacted strongly though with varying rapidity. When this serum was combined with emulsions of the colon bacillus, no reactions occurred, nor did any of the nineteen races of typhoid bacilli react to colon serum. In the colon experiments they employed one colon serum and ten cultures of colon bacilli from different sources, among them several from a case of fatal peritonitis. These different races of colon bacilli did not all react with colon serum, but it is noteworthy that not one of them exhibited the slightest reaction to typhoid serum.

Table No. 1.

Number.	Disease.	Reaction.	No Reaction.	Period of Fever.	Remarks.
1........	Typhoid.	..	1	9th day.	
2........	"	1	..	10th day.	Clinical diagnosis doubtful at time of test.
3........	"	1	..	21st day.	
4........	"	1	..	14th day.	Clinical diagnosis doubtful at time of test.

27........	"	..	1	7th day.	Developed undoubted typhoid.
28........	"	1	..	Several weeks.	

From the foregoing it appears that several investigators had observed and demonstrated the reaction of motile bacteria with their own sera, and in typhoid fever and cholera the serum of convalescents had been found to work equally well with that of artificially immunized animals. The value of the phenomenon as a method of identifying doubtful races of germs, and, *vice versa*, of diagnosing the disease, had been discussed; but it remained for Widal to make the phenomenon of practical diagnostic value by demonstrating that the serum of typhoid patients possesses this peculiar agglutinating quality as early as the fifth day of the disease, and very generally by the eighth or ninth day. He believes the clumping to be an infection, and not an immunity, reaction. Widal describes two methods of diagnosis which he recommends to be carried out concurrently. A brief description of the methods is in order, inasmuch as they are practically those adopted by all present investigators on the same line.

---

[1] *Journal of Path. and Bact.*, vol. iv, No. 1.

First Method.—Draw a few drops of blood from the end of the finger. Mix the separated serum with ten parts of a one-to-two day typhoid bouillon culture. Observe with the microscope from one-half to several hours. If large clumps of motionless bacilli gather and the areas between are free or almost free from bacilli, the case is typhoid.

Second Method.—Draw about 5 c.cm. of blood from the median vein of the arm with a sterile syringe. Mix ½ c.cm. of serum with 4 c.cm. of typhoid bouillon culture. Incubate at 37° C. for twenty-four hours, when the reaction will be complete. (Breuer[1] notes that if the active serum is added to a twenty-four-hour typhoid bouillon culture the reaction will be plain in eight to twelve hours but less so at the end of twenty-four hours. If the bouillon is inoculated with typhoid bacilli at the same time the serum is added, it requires about twenty-four hours for the reaction to reach completion). To Widal must also be given the credit of having first stated that dried serum and, to a lesser extent, dried blood are capable of furnishing the reaction. His results and those of his followers in France have been so uniformly successful that they have inspired widespread confidence in the infallibility of the method. R. Stern,[2] in a review of Widal's report, says that the latter found the reaction present as early as the fourth or fifth day. He missed it once on the sixth but found it on the seventh day. All non-typhoids gave negative results. The reaction was most intense after the drop in the fever, but there was no proof of relation between the strength of the reaction and the severity of the disease.

Dr. Johnston,[3] independently of Widal, deduced from the fact that substances, such as the toxins and antitoxins (analogous to the agglutinins) preserve their charcteristics in a dry state, that the same might be true of the substances causing the serum reaction. He therefore examined specimens of dried blood from ten typical cases of typhoid and found the reaction to be complete in every instance. As control cases he examined the dried blood from a number of healthy persons, and from ten hospital patients suffering with other diseases than typhoid. In none of these did he get a reaction, except an "occasional pseudo-reaction" which he described as a partial agglutination and loss of mobility which was regained in an hour or two. Two doubtful cases failed to give the reaction, and subsequent developments proved that they were not typhoid. He concludes that this method is "just as efficacious as the pure serum method for the diagnostic purposes of the test," and recommends its use in public health bureaus to the end that typhoid cases may be earlier and more generally reported.

Such, then, is the history in brief of the development of the Widal method of serum diagnosis. I have yet to find a report of an experimenter who questions the specific nature of the reaction, provided the procedure recommended by Widal is carried out, and the reaction is tested both microscopically and in gross. Indeed, according to report it may be laid down almost as an axiom that if diluted sixteen times, the serum of typhoid is the only one giving a distinct agglutinative action with the typhoid bacillus. Unfortunately, the dried blood method brought forward by Johnston cannot claim the same degree of trustworthiness, nor can the microscopic examination of any emulsion in which the serum is used in low dilution. It is doubly unfortunate because the method is so simple that it could be rapidly introduced into general use. On the other hand, few physicians would care to subject their patients to a venesection, and even the simple capillary glass tube would be less used.

Before passing to the consideration of my own cases I wish to mention a few reported quite recently by other investigators. R. Stern mentions a case of otitis which, with the serum dilution of one-to-twenty, gave a typical reaction with typhoid bacilli in less than one hour. The patient had never had typhoid. R. Breuer, who is enthusiastic in his recommendations of the gross method, reports poor results with the microscopic method of procedure. He says his results with the latter were not clear or satisfactory—not to be compared with the former. "Reaction seldom occurred before 15 to 30 minutes and in that time, usually, the sera of other fever patients caused distinct agglomerations." He says, further: "In my hands this variety of the method (microscopic) impressed me as untrustworthy." He reserves his judgment, however, in view of the preference for and confidence in that method in France among the disciples of Widal, but calls attention to the fact that the latter recommends the use of the microscopic method together with the gross method as a control. He reports no individual cases tested microscopically, having confined experiments almost exclusively to the gross reaction.

TABLE NO. 2.

Number.	Cases.	Reaction.	No Reaction.	Remarks.
1	Phthisis	1	..	Cough, high fever, emaciation. No history of typhoid previously. Fresh specimen of blood one month later reacted at once.
2	Rheumatism	1	..	Reaction in five minutes. Repeated with fresh blood three weeks later.
3	Malaria	1	..	Fever the only symptom suggesting typhoid.
4	Tuberculosis	..	1	
5	Pneumonia	..	1	
6	Tuberculosis	..	1	
7	Syphilis	..	1	Secondary.
8	Tuberculosis	..	1	
9	Syphilis	..	1	Secondary.
10	Mumps	..	1	Convalescent.
11	Rheumatism	..	1	
12	Pneumonia	..	1	Third week.
13	Pleurisy	..	1	
14	Cerebral abscess	..	1	
15	Puerperal fever	..	1	
16	Doubtful	..	1	Temperature 99°–104° F. Two small hemorrhages from bowels. Temperature normal and rapid improvement after removal of ovarian cyst. No reaction one month later.
17	Malaria	..	1	Tertian form.
18	Scarlatina	..	1	
19	Pleurisy	..	1	Suspected typhoid at first.
20	Endocarditis	..	1	
21	Old typhoid	1	..	Had typhoid three years ago. Reaction in one hour.
22	" "	1	..	" " six " " " " "
23	Typhoid	..	1	" " ten " "
24	Old typhoid	..	1	" " six " "
25	" "	..	1	" " four " "
26	" "	..	1	" " sixteen " "
27	Normal serum	..	1	Guinea-pig's blood.
28	" "	..	1	Human blood.
29	Antitoxin	..	1	Serum of horse, 100 units.

Most unfavorable of all is the report of A. S. Gruenbaum[1] giving results of his tests conducted in Vienna. He used the microscopic method without regard to the ratio of dilution of the serum. As appears in the appended table, eight typhoid patients, and five who had had typhoid from five to thirty-seven years previously, gave the reaction, but so did also fifteen out of twenty-four patients suffering from miscellaneous diseases other than typhoid. It is a curious fact that all the jaundice cases tested gave a strong reaction with typhoid bacilli. Favorable to the dried blood method are the reports of Johnston—ten typhoids with uniform reaction, and ten non-typhoids with no reaction; and C. L. Greene,[2] twenty-seven typhoids with uniform reaction, and thirty-three non-typhoids with no reaction.

My own series of cases, collected from several hospitals and private practitioners of Brooklyn with the special end in view of testing the reliability of the dried-blood method, contains a few that also militate seriously against the usefulness of that procedure. The blood was in most cases dried on glass slides or pieces of paper before being sent to the laboratory. The usual precautions were observed, such as examining controls to see if the bacilli were not already clumped, preserving a nearly uniform temperature for the reaction, and examining the lower part of the drop under inspection, for clumps. A drop of distilled water was added to and mixed with a drop of dried blood. This was transferred to a cover-glass and a drop of an emulsion of typhoid bacilli in filtered water added to it. The glass was then sealed with vaseline over a hollowed glass slide and observed at intervals during one or two hours, and again at the end of twenty-four hours. In the great majority of instances the reaction occurred, if at all, in from one to thirty minutes. Two races of typhoid bacilli were used in the tests, one of the same race as those used by Professor Pfeiffer in his original experiments, and the other recovered by Dr. Wilson from the spleen of a fatal case of typhoid. The latter was subjected to all the important differential tests and its identity established beyond a doubt.

Case No. 3 of Table No. 2, a hospital patient, disease diagnosed as malaria and having no other symptoms of typhoid than remittent fever of two weeks duration, gave a clear reaction.

---

[1] *Lancet*, September 30, 1896.
[2] *N. Y. Med. Record*, November 14 and December 5, 1896.

Case No. 2 of Table No. 2, of acute rheumatism, at St. John's hospital, gave the reaction in five minutes with both typhoid cultures. The test was repeated with a fresh specimen of blood three weeks later with the same result.

Case No. 1 of Table No. 2, of advanced tuberculosis, at the U. S. Naval Hospital, gave a doubtful reaction. One month later the reaction was marked and immediate. The patient could remember no sickness of recent years lasting longer than one week. Of the other twenty-six cases of non-typhoid contained in Table No. 2, all but two gave no reaction, and these had had typhoid three and six years before, respectively. Four other cases having had typhoid four, six, ten, and sixteen years previously, failed to give the reaction.

The cases diagnosed clinically as typhoid, or later developing typhoid symptoms, I have collected in Table No. 1. There are 28 of these, and 4 failed to give the reaction. One of the latter was examined on the sixth day of the fever, 2 on the seventh, and 1 on the ninth. The remaining 24 cases gave the typhoid reaction, and of these 2 were examined on the seventh day, 1 on the eighth, 1 on the ninth, 4 on the tenth, and the rest from the twelfth day to the second week of convalescence. In most of the cases typhoid had been already diagnosed at the time of the test, but in 5 the diagnosis was doubtful, and the test added a little weight to the proper arm of the balance.

The sera of 11 typhoids and 11 non-typhoids was tested with a culture of the colon bacillus, and the results were rather surprising in view of the results reported by Durham. A reaction took place in all of the 22 tests, more marked and rapidly developed in the typhoid sera, but distinct with the others. In all cases the reaction persisted during the time of observation, from one hour to twenty-four hours. The behavior of this race of the colon bacillus is most interesting and suggests a wide range of susceptibility in different races of the same species of bacteria. None of the 10 races of the colon bacillus used by Durham in his experiments reacted in the least to his typhoid serum. The same variation of susceptibility in typhoid cultures will be noted later.

Adding to my own the cases reported recently by Johnston, Stern, Gruenbaum, Breuer, and Greene, and collected by me in Tables Nos. 3 and 4, we have a number sufficiently large to make a fair basis for criticism and deduction. As is noted in the tables, the tests were made by some in gross and others microscopically; some with dried blood and others with serum. In all, 132 typhoids were tested, of which 1 gave a doubtful reaction, and 4, examined on the sixth, seventh, and ninth days, no reaction. One hundred and twenty-nine non-typhoids were tested, and of these 26 gave a reaction (7 having had typhoid from three to thirty-seven years previously), 5 a doubtful reaction, and 98 no reaction.

What conclusions are we justified in drawing from these figures? Considering my own results, and the more striking results of Breuer and Gruenbaum, I feel convinced that the method recommended by Johnston of testing dried blood in low and indefinite dilution contains too many sources of error to warrant its use as a method of diagnosis. Many varieties of serum in low dilution have been found to cause a reaction with typhoid, colon, and cholera germs. If in a given case the test be negative we can only report that it is either too early in the course of the disease to enable us to obtain a reaction, or that it is not typhoid; if the test be positive, that it is probably typhoid but may be something else. Fortunately, we have the promise of a more accurate and conclusive method, which I expect to use in a later series of experiments in this connection. Widal recommends a dilution of the serum 1–10 to 1–15, and Gruenbaum makes the statement that if diluted sixteen times the serum of typhoid is the only one giving a distinct agglutinative action with the typhoid bacillus. Widal states that at the height of typhoid the serum is active at a dilution of 1–60 to 1–80, and Stern states that in seven of his typhoid cases the serum was active at 1–100 to 1–2000. The serum of non-typhoids is said to lose the power of reaction very rapidly after three or four dilutions.

TABLE NO. 4.

Cases.	Number Reported.	Reaction.	No Reaction.	Dilution.	Method and Remarks.	Reported by:
Miscellaneous..	10	..	10	Indefinite......	Dried blood..................................	W. Johnston.
Otitis	1	1	..	1–20..........	Microscopical and Macroscopical. Patient never had had typhoid...........................	R. Stern.
Normal.......	5	5	..	Indefinite......	Had had typhoid 5–37 years before.............	Gruenbaum.
Miscellaneous..	24	15	9	"	Cholera vibrios reacted with 16 out of 29 cases, and colon bacilli with 3 out of 3. All jaundice cases gave strong reaction with typhoid bacilli.	"
Miscellaneous..	27	..	22	.5–4 c.cm	Macroscopical. Five gave a pseudo reaction.....	R. Breuer.
Miscellaneous..	33	..	33	Indefinite......	Dried blood..................................	C. L. Greene.

These matters of dilution and of culture susceptibility I believe to be of the utmost importance in testing for reactions, and unless the working errors dependent on them be reduced to a minimum we shall not be very sure of our results. If Widal's culture reacts to no higher dilution than 1–80, while Stern's culture reacts as high as 1–2000, it requires no effort of the imagination to believe that susceptibility may vary as much in the other direction, and that another person experimenting with an insusceptible race of germs might obtain negative results where they should obtain positive results. Pfeiffer and Kolle found cholera germs very variable in susceptibility to a given serum.

It is therefore of the greatest importance that the stock culture with which one is to work should, as a preliminary, be tested with a serum of known potency; and, furthermore, it is indispensable that the ratio of serum to typhoid culture should be fixed at a point where the serum of non-typhoids is surely incapable of reaction. With attention to these details, which is obviously impossible when one examines a specimen of dried blood, we may hope for less variable reports from those experimenting upon this line in the future.[1]

DISCUSSION.

Dr. W. H. Park of New York said: I have listened with great interest to the paper by Dr. Thomas. Like him, I have been making daily examinations of specimens of blood from suspected cases of typhoid fever. As to the method of examination, I agree with the opinions expressed except that I require the reaction to occur within even less time than he does. To be of value in establishing a diagnosis of typhoid fever, I believe that the bacilli should show upon the mixture with the serum an immediate inhibition of movement and a marked tendency to clumping. With dried blood solutions I believe that the reaction which occurs after fifteen minutes is often misleading. As Widal's serum test is quantitative rather than qualitative, we must use not more than one part of serum to nine of culture; otherwise, we will get reactions from non-typhoid cases. For practical purposes, examinations made from dried blood are nearly as reliable as from serum. For experimental purposes, the fluid serum is far better, as allowing more accurate dilutions. It can be obtained from blood or blisters.

The results obtained by me, and by the other workers in the laboratories of the New York Health Department, have agreed with those of Dr. Thomas. A definite reaction has been present in about seventy-five per cent. of the cases upon the first examination. It usually appeared by the sixth or seventh day. Regarding the duration of the reaction, I first feared that it would persist so long in the patient that it would interfere greatly with the value of the test in making a positive diagnosis. My experience has been, however, similar to that of Dr. Thomas. In very few does the reaction exist for over a year to such a degree as to interfere with the value of Widal's test for the present illness. As to whether the reaction occurs in other cases than typhoid, and if so, how often, we will have to wait for many more examinations. Dr. Thomas's case of phthisis, in which the reaction developed during the disease, would indicate that in exceptional instances the reaction may develop in non-typhoid cases.

---

[1] Since writing the above I have read a circular issued by Dr. Johnston under date of January 7, 1897, in which he reports modifications of his method that render it less open to criticism. He states that he has recently met with a number of normal cases in which the serum causes a decided agglutination. By using attenuated cultures of the germs he finds that the reaction takes place with typhoid serum only. He also advises dilution of the mixture of dried blood and typhoid emulsion till it retains only a faint tint of the red. These modifications make the process more reliable, in my opinion, and the attenuation of the bacilli acts in a manner similar to the definite dilution of the serum which I have emphasized. I believe, however, that the latter procedure is the more accurate. By drawing a few drops of blood from the patient's finger in capillary glass tubes, separating the serum and mixing it with a definite amount of filtered water in a graduated capillary tube (Gruenbaum) a maximum degree of accuracy is attained and the procedure remains simple enough for general use as a diagnostic test.

I have myself met with three colored persons whose blood gave a decided reaction. These three all had continuous fever for from eight to ten days, but no other symptoms of typhoid fever. In none of them was the cause of the fever discovered, and they may have had irregular typhoid fever. It is possible that even in the case of phthisis reported by Dr. Thomas intestinal ulcerations may have been present, and possibly a slight typhoid infection have occurred. A definite typhoid reaction with blood or serum, one part to ten or more of culture, certainly rarely occurs, except with that from typhoid patients or convalescents. It seems to me that the results so far obtained warrant us in attributing great diagnostic value to a positive typhoid reaction. The absence of the reaction in a single test has little value. It does not exclude typhoid fever. Repeated negative results in a single case, or negative results in a number of similar cases, would have very great value, however, in excluding typhoid fever.

THE EXTRACTION OF TOO LONG RETAINED SILK AND SILKWORM GUT LIGATURES AND SUTURES.

By ROBERT F. WEIR, M.D.,
OF NEW YORK;
SURGEON TO THE NEW YORK HOSPITAL, ETC.

ALTHOUGH it is widely recognized at the present day that silk and silkworm gut may provoke or keep up suppuration and a sinus, yet the security attained from the use of these materials is so much beyond that afforded by catgut, however treated, or by kangaroo tendon, that many surgeons still employ them, particularly in regions where the breaking of a ligature or its too early relaxation might embarrass the operation, or, more rarely, endanger the patient. Many operators, for instance, prefer in ovariotomy, in vaginal hysterectomy, in castration, in nephrectomy, and similar operations, to rely upon a silk ligature rather than on catgut, particularly since the larger catgut required is so often difficult to render free from germs. It is only of recent years (and indeed, not always now) that the appendical stump is tied off by catgut, which is sufficient, rather than by silk, since this tube is easily compressed, and its temporary closure by the ligature is perfected in a few hours by rapidly forming peritoneal adhesions. When silk was used, not infrequently the sinus that persisted was found to be due to the retention of the ligature about the appendix, and I confess after I had abandoned silk for catgut in this operation, that some of Jack Horner's spirit often arose within me as I fished out, with the homely contrivance which is represented in Fig. 1, the offending loop left in by another operator.

The vagaries of the ovarian silk ligatures are many, and so well known as to merit only an allusion to them. Silkworm gut is almost germ proof, and lasts indefinitely. I have extracted unchanged, a suture of this material seventeen months after its introduction into a wound. As a rule, it is well borne when used as a buried suture, but when its track is invaded by a germ infection, it acts as a foreign body. For special care in closing up the freshly cut deep abdominal fascia, in my judgment, the closely applied one-fourth-inch apart fine silkworm gut suture is not equalled by any other, not even by the kangaroo tendon suture. Though per contra, in the ordinary hernia operations where the tissues are loose and are often torn rather than cut, and where, hence, possibilities of a suitable germ soil exist, the kangaroo tendon works better. To this, however, I make the exception in the cases of recurrent hernias, or those with large openings, where I prefer yet to rely on the persistent silkworm gut suture, rather than the kangaroo tendon, which does not last as long as is generally supposed, a number of trials in my hands having shown that it rarely endures beyond fifteen or twenty days.

FIG. 1.

Crochet-needle of Bone or Steel.

Returning to the gist of these remarks, I ask attention, in the extraction of a sinus-producing buried suture, whether of silk, silkworm gut, or even of wire, to the use of the ordinary crochet-needle, made either of bone or steel, which can be bought almost everywhere, and at a cost of a few cents. The hook end, if too sharp, can be dulled with the edge of a file. For special cases I have had some steel ones made larger than could be bought, and also some that could be bent to accommodate the curves of a sinuous track. But with the use of this common implement a suture can often be caught, dragged to the surface, and seized by forceps, when it may be cut and extracted. Its need and its use is so self-evident that I fear that I am only telling a twice-told tale. In the cases where, in full cognizance of the evils of a silk ligature, I nevertheless have employed it, for instance, as the most important, in lumbar nephrectomy for pyonephrosis, I have usually left one or both ends of the ligature hanging out of the wound. The coming away of these ligatures may require from three weeks to three months, even though digital traction may be made from time to time. In one case just completed, the ligature still held at the end of the tenth week. In another operation two months since, the ligature remained *in situ* four weeks after the operation. I had in cases before these used the crochet-needle, but in the first of these last two nephrectomies I learned of a risk that does not usually exist in other localities. The needle in its introduction must have passed beyond the ligature, for in its withdrawal it caught in one of the renal veins and tore it, when a fierce hemorrhage occurred which momentarily alarmed me, though it was soon checked by firm pressure. I was therefore unwilling to try this plan again in that case, and began traction on the ligature by a rubber band to which was attached a two to four-ounce lead sinker. This, by gravity, the patient being up and about, cut the edges of the cicatrix, and its use was abandoned. Then the contrivance shown in Fig. 2 was employed, with excellent success. The ligature end was passed through a small rubber ball (costing 5 cents) and fastened, after squeezing the walls of the ball together, on its outer side. The thus flattened ball exerted pressure directly outward, and the only mishap that occurred was due to the counter pressure the ball exerted on the covered cicatrix. This was obviated by passing a piece of thin basswood splinting, duly padded, between the wound and the ball. After five-days' use of the traction, which was not particularly painful, the ligature came away. In the second nephrectomy, where the rubber-ball traction was similarly applied, the ligature came away in a week's time. In a third and fourth nephrectomy performed since then, I resorted, however, to a method which is even better than the foregoing one, but which requires more ample resources. The suggestion of it is due to Dr. Clement Cleveland, who showed at the meeting of the Practitioners' Society in May, 1896, some wire loop electrodes similar to those used for laryngeal cauterization. These he had used with success in freeing at will the silk ligatures employed in vaginal hysterectomy. At the operation the silk ligature is

Cleveland's Cautery Wire Adjusted for Severing the Ligature.

passed through the base loop of the otherwise insulated electrode, and its ends pass out of the wound alongside the wires of the electrode. At the desired time, a galvanic cautery battery of weak power heats the little loop sufficiently to burn through and liberate the ligature. This plan was used by me in both of these nephrectomies with a most satisfactory issue, and left nothing to be desired. But in the absence of an electrode and a battery, I venture to commend the little expedient of the compressed rubber ball as simple, ready, efficient, and cheap. Mechanical hints of value often come from the patient himself or his friends. This was instanced in the second case of delayed ligature, as I was presented by the brother of the patient with the device of a spring tractor attached to a broad padded piece of wood with a spring of four-ounce traction power, and with a little ratchet capable of rendering taut the ligature emerging from the wound, but the rubber ball acted efficaciously and the contrivance was not tested.[1]

CLINICAL MEMORANDA.

EXCISION OF THE PRIMARY LESION OF SYPHILIS.

By WILLIAM P. MUNN, M.D.,
OF DENVER, COL.;
PROFESSOR OF GENITO-URINARY DISEASES IN THE UNIVERSITY OF DENVER.

THE effort to abort syphilitic infection by the excision of the initial lesion as soon as recognized has been frequently made, but, as a rule, without positive results. When the nature of the infection has been undoubted, secondary manifestations have occurred at the usual time. In cases where no secondary signs have made their appearance there has usually been some doubt cast upon the nature of the original infection.

The case here reported may be open to some doubt, although to me the preponderance of probability is in favor of the original infection being syphilitic.

A., about fifty years of age, married, is the father of perfectly healthy children, and has no history of previous syphilitic infection. About February 6, 1896, he had irregular sexual connection. The woman, he says, appeared to be healthy and presented (to him) no evidence of syphilis: she was not a prostitute. On February 21st, he presented himself for treatment of a sore which had appeared on his prepuce a few days before. The probable time from the date of connection to the time of the appearance of the sore was twelve days.

The sore was located on the prepuce at the junction of skin and mucous membrane; it was about one-fourth of an inch in diameter, was sharply outlined, and had exact edges which were completely indurated. The surface of the ulcer was bright red and was almost free from secretion. The patient had no fever, and there was no lymphatic involvement.

The physical appearances were absolutely characteristic of the initial lesion of syphilis although the time of appearance was a little shorter than we usually expect to elapse before the complete development of such a lesion. The patient was kept under observation for two days, and there was no increase in the amount of secretion, or change in the other physical characteristics of the sore. It was then decided to remove it freely by circumcision. This was done under chloroform anesthesia, and there was complete primary union of the circumcision-wound, although slight infection of one stitch hole occurred.

The man has been under careful observation ever since, being seen at intervals of about one month. At this date, one full year from the time of infection, there is no evidence of any of the secondaries of syphilis, nor has his general health at any time during the year been below par, except from a temporary manifestation of spinal symptoms at the location of an ankylosed lumbar trouble, dating from childhood. His skin is clear and clean; the mucous membrane of the mouth has at no time shown any evidence of patches; his weight has increased. The specimen removed was submitted to Dr. H. C. Crouch for microscopic examination, and he reported that it was in all probability an initial lesion of syphilis.

TRANSPERITONEAL LIGATION OF THE EXTERNAL ILIAC ARTERY FOR FEMORAL ANEURISM, WITH SUBSEQUENT DISSECTION OF THE SAC.[1]

By N. P. DANDRIDGE, M.D.,
OF CINCINNATI.

I WISH to report in the following paper a case of aneurism of the common femoral artery, which was treated by ligation of the external iliac artery, and the laying open of the sac and its partial removal by dissection after the ligation of the superficial and deep femorals. I should not consider the recital of a single case as of sufficient importance to engage the attention of the members of the Society did it not illustrate some of the questions now pressing for solution in connection with aneurism of the extremities. The facts of the case are as follows:

J. W. B., aged thirty-nine, colored, a laborer, entered the Cincinnati Hospital September 26, 1896. There was a history of rheumatism, and he admitted having had syphilis ten years ago. He has had gonorrhea twice, and is a moderate drinker. In May, 1896, he noticed a "lump" in the left groin, which throbbed and gradually attained the size of a hen's egg, and for three weeks he was obliged to abandon his work on account of the severe pain. His knee was drawn up and he could not walk. The tumor then became smaller, and he went back to work. Three weeks before entering the hospital, while carrying a hod up a ladder, he felt something give way in the left groin. He stopped work the same day and went to bed, there being severe pain in the leg. From the time of the "snap" the tumor constantly increased in size, the knee was drawn up and he was unable to straighten it. The pain became so severe that he decided to come to the hospital.

---

[1] Since writing this paper I have seen described a method of using "traction" ligatures, which has been introduced by Dr. Grad of the Woman's Hospital, New York, which is superior to any device yet presented. He places under each tie of the knot a loop of silk, having thus for the ordinary knot two loops, and for a triple knot three loops, or tractors. One end of the ligature proper is cut short, and the other passes out of the wound. At the chosen time traction is made on the last applied tractor, and the last made turn of the knot unties. Tractor No. 2 is then pulled upon with a similar result, and finally tractor No. 3 disengages the first turn of the knot, when a light pull in turn on the ligature proper, disengages it, and its removal is allowed. A full account of this ingenious method is published, with explanatory figures, in the *American Gynecological and Obstetrical Journal* for February, 1897, with illustrative cases to which it had been applied.

[1] Read before the Southern Surgical and Gynecological Society, Nashville, November, 1896.

On admission, the knee was found drawn up at an angle of 45°, and the power of straightening it was lost. The severe pain was constant. In the left groin there was found a smooth, elastic, circumscribed pulsating tumor, 5 inches in the long diameter, and 3½ inches in the short diameter. The pulsation was expansile, and a well-marked thrill could be felt over the inner aspect. The tumor occupied Scarpa's triangle, reached fully up to Poupart's ligament, and outward as far as the spine of the ilium, and with the stethoscope a distinct bruit could be heard over its entire area. No pulsation could be found in the anterior or posterior tibial arteries at the ankle. It was evident from the condition present, and the history given, that we had to deal with an aneurism of the common iliac artery dating back probably to the accident in May, some six months, and which had become diffused at the time of the second attack, three weeks before the patient entered the hospital. The man was kept quiet in bed, on low diet, and iodid of potash was given. The swelling, with the transmitted pulsation, continued to increase steadily upon the outer and upper aspect, until it reached above and beyond the anterior superior spinous process of the ilium, and the pain continued to be severe. It was thus apparent that immediate operative interference was required. It was equally evident that ligation of the external iliac would be necessary to control the current of blood into the sac, as the aneurism involved the end of this artery as well as the common femoral. It was further apparent that the ordinary extraperitoneal operation, by an incision above and parallel to Poupart's ligament, was out of the question, as the pulsating swelling had already reached above and beyond the anterior spinous process and had invaded the iliac fossa. It was decided, therefore, to apply the ligature from within the abdominal cavity.

Seven days after admission, on October 5th, under ether anesthesia, a median incision about four inches in length was made, with the man in the Trendelenburg position. The external iliac artery was easily located by its pulsation, and an incision through the peritoneum, an inch or more in length, on its outer side readily exposed it. An aneurism needle armed with kangaroo tendon was passed from within outward and the vessel secured. Pulsation in the tumor at once stopped. The opening in the peritoneum over the iliac artery was closed by a fine silk suture, and the abdominal wound was then closed. An incision some six inches in length, reaching from above to a point below the swelling in the groin, was now made. When the sac was reached it was exposed by reflecting the overlying tissues with the handle of a scalpel. A free incision then laid open the aneurism, from top to bottom. A large amount of fluid blood gushed out at once, leaving some laminated clots, and exposing to view the fibers of the pectineus muscle, showing that the sac had given way. The cavity thus made by the escaping blood reached well into the iliac fossa. Free hemorrhage at once occurred from below, from the openings of the superficial and deep femorals, which were both within the area of aneurismal dilatation, and from a small vessel above. A probe passed from the opening in the sac-wall, located the superficial femoral in the matted tissues below and enabled us to pass a ligature around it, but in so doing the vein was wounded, and it became necessary to secure it by a ligature which included the artery as well as a considerable mass of tissue. The deep femoral artery was isolated and secured outside of the sac, and the bleeding points above were clamped by hemostatic forceps, which were left in place two days. As much as possible of the sac, about one-third, was then separated by blunt dissection and removed. The wound cavity was packed with iodoform gauze, which was brought out at the lower end of the incision, and the upper portion of the wound was then closed by suture. The entire limb was wrapped in cotton. There was a good deal of numbness complained of in the leg, and it became necessary to use the catheter for several days.

The abdominal wound healed by first intention. The wound over the tumor healed except at one point in the middle and at the lower level where the gauze-drain had been. On the fifth day a serous oozing occurred from the first of these openings. The discharge subsequently became purulent, and as the pus came from a pocket which could not be drained, the patient was again placed under ether and the cavity was laid open. The remnant of the sac was found to be in a sloughing condition, and there was a quantity of pus which had dissected out a cavity of large size. This was on November 5th, thirty-one days after the first operation. The cavity was drained by a counter opening upon the outer aspect of the thigh, a drainage tube being passed through to the front incision. The wound was left open and the whole cavity packed with strips of gauze. Four months after the operation the discharge had ceased. There remained, however, a complete paralysis of sensation over the anterior aspect of the thigh, and inability to extend the leg on the thigh. It is probable that some branches of the anterior spinal nerve were cut in laying open the sac.

In commenting on the course adopted in this case, the following facts should be made prominent. Ligation of the iliac artery was clearly necessary, as no form of pressure offered any chance of success. The invasion of the iliac fossa by the dissecting blood made it probable that the aneurism itself could not be opened by the usual extraperitoneal incision. It was therefore deemed necessary to secure the artery by opening the abdomen. The median incision was chosen, as it gave freer access to the artery, so that the ligature could be placed as high as was necessary, and because it would be further away from the opening in the aneurism which it was proposed to make than if we approached the artery by the lower part of the linea semilunaris, and which would therefore have been more liable to infection if suppuration should occur in the sac. The propriety of opening the sac was shown by the free hemorrhage which occurred from the openings of the superficial and deep femoral arteries, both of which were involved in the aneurismal expansion of the common femoral. This bleeding was only controlled by ligation of both vessels. If not thus secured, they would certainly have continued to discharge blood into the aneurism in sufficient quantities to cause its continued expansion. This part of the operation would have been much facilitated had we thought of throwing an elastic tourniquet around the thigh below. All bleeding could have been controlled, the arteries isolated, and the sac entirely dissected out. That complete, instead of partial, removal was desirable, is indicated by the suppuration and sloughing of the part left behind, which most certainly started from the remnant in place. The wound in the vein was not followed by any bad results.

I would formulate the following as the proper steps in an operation for aneurism of the groin situated so high that the common femoral cannot be secured: (1) Ligation of the external iliac by the transperitoneal route, through a median incision, with immediate closure of the wound in the abdominal wall. (2) The application of an elastic tourniquet about the middle of the thigh. (3) Free opening of the sac from top to bottom, and the removal of all clots, and the subsequent ligation of all the large arteries found opening from it, and then careful, complete extirpation by dissection and curettage. This will, I believe, be found much easier than the attempt to dissect out the mass entire before opening the sac. After opening, the different vessels can be located outside the sac by passing a probe along their course through the openings. Such vessels are often difficult to isolate. The vein should be spared if possible, but if this cannot be done it should be cut between two ligatures. Important nerves will be more easily avoided.

Bolton, in his article on "Special Aneurisms," in Dennis' "Surgery," vol. ii, page 414, says that "extirpation of the sac has twice been undertaken" in aneurisms of the groin, once by Rose in "an aneurism which had recurred two years after ligation of the external iliac," and once by Bazy, "who extirpated a large aneurism with success after tying numerous large afferent arteries." The same author, quoting from Delbet's statistics, gives 67 cases of ligation of the external iliac artery for aneurism of the groin, with 42 cures and 25 failures. There were 13 deaths (2 being due to accidental causes) in these 25 cases, and in the remaining 12 there was no change in 5, in 5 suppuration ensued and a cure resulted, in 1 gangrene required amputation, and in 1 secondary hemorrhage required a second ligation, and ended in cure. In estimating the advantage of extirpation of the sac, reference may be made to these figures. Thus, in these 67 cases, the aneurisms remained unchanged in 5, in 1 secondary hemorrhage occurred in the sac, and in 5 suppuration occurred. Suppuration in the sac is one of the recognized dangers if the sac is left. Such a complication, of course, would not take place after extirpation. In 5 cases no changes occurred in the aneurism after simple ligation. Extirpation of the sac may compromise the veins, though not necessarily so, and there is sufficient experience now to show that this is not of much importance. Furthermore, recurrence of the aneurism may take place even years after simple ligation. Extirpation of course provides for this.

Hubler (*Beitrage zur klin. Chirurgie*, Tübingen, May 28, 1892) has collected 40 cases of complete extirpation of aneurism from different sources. Twenty-eight of these were arterial, and 12 arterio-venous. Twenty-nine were traumatic, and 11 non-traumatic; in 18, the lower limb was affected, and in 16 one of the upper. These cases were all successful except one. In none of these cases was there any mention made of gangrene or secondary hemorrhage. If the common femoral artery can be reached in aneurism of the groin, a ligature should be placed upon it, and then the extirpation proceeded with as above. In cases of aneurism of the superficial femoral artery digital compression gives such favorable results and is attended by so little danger that it should first be tried, and if not successful ligation and extirpation should be proceeded with. The intimate relation of popliteal aneurisms to the overlying nerve and vein, and the proximity of the joint make extirpation extremely dangerous, so that ligation at a distance should probably be tried (in case compression of the femoral fails in place of extirpation) unless the aneurism is of very large size.

CLINICAL LECTURE.

THE NATURE AND OPERATIVE TREATMENT OF HYDROCEPHALUS; DRAINAGE FROM THE LOWER END OF THE SPINAL CANAL; REPORT OF A CASE.[1]

BY ROSWELL PARK, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

I SHOW you an infant, three months of age, suffering from a typical case of hydrocephalus of distinct type, which is not so far advanced as to make it necessarily or certainly hopeless. This is the first child of healthy parents, the mother being much younger than the father. The mother's pregnancy and delivery were normal, and the child was a month old before she suspected that anything serious was the matter, and took him to a physician. She consulted Dr. Woodbury, who kindly referred the case to me. Even at that time there was a disproportion between the upper and lower portions of the head, and the eyes were somewhat prominent. After the indications of hydrocephalus were complete, the child had a little accession of temperature, and remained listlessly in its mother's arms. I suggested the use of potassium iodid, with the hypophosphites, as a tentative measure, while the parents were considering the advisability of an operation. In view of the progress of the disease, they have made up their minds to submit the babe to anything that affords the slightest hope of relief of the condition; and it is here to-day for operation.

---

[1] Clinical lecture delivered at the Buffalo General Hospital.

The therapeutic and medical aspects of the malady have been discussed elsewhere, and consequently I confine myself to considering its pathology and surgical treatment. First, we divide these cases into the *congenital* and *acquired* forms, with the statement, however, that as occurring in the very young a very large proportion of them belong to the congenital type, an explanation of the occurrence of the affection being afforded by some deviation from the normal arrangement of the brain and its cavities originating during the development of the fetus. We must distinguish also between the truly congenital and postpartum hydrocephalus. The acquired form may be observed alike in children and adults, and may be due to syphilis, tuberculosis, or rickets. Next we speak of hydrocephalus *internus* and *externus*, the former being much more common, and including those cases in which the ventricles are distended with fluid, for the most part the lateral ventricles, but occasionally the fourth and fifth. In the latter type the collection of fluid is mostly between the brain and the expanded skull. In a hundred cases of so-called hydrocephalus, about eighty per cent., if not more, will be of the congenital type and the internal variety. In many instances, when the development of the brain is notoriously defective, there will be corresponding defects in other parts of the body. The tendency of the disease is toward an early death, most of these children dying soon after delivery. None of the theories yet advanced, however, account for all the lesions noted in many cases, such as the widening of the occipital foramen and spinal canal, and certain defects in the central nervous system. In adult cases, separation of the cranial bones is not possible. This occurs for the most part in rachitic children in whom the skull expands by degrees until it is capable of holding a relatively enormous amount of fluid, even several hundred cubic centimeters.

Among the causes of hydrocephalus we will place, first, defects of development which permit distention to a degree varying with the nature of the defect. Next, we have to do with the accumulation of ventricular fluid as the result of meningitis, encephalitis, tuberculous disease, or atrophy of the brain. In the latter case it is essentially a *hydrops ex vacuo*. The extreme forms of hydrocephalus may be due to pachymeningitis internal, which may produce a subdural exudate, in which case the collection of fluid is diffuse; or to some local lesion by which we have an encapsulated collection of cerebrospinal fluid, which is afterward known as hygroma of the dura. Often in a case thus localized, when occurring in the young, we may have an expansion of the overlying portion of the skull.

In this particular instance we have undoubtedly to deal with a congenital or postpartum form of the condition which has assumed from the outset a chronic course, as it usually does, but which tends steadily to disaster, since the little patient is already showing the effects of brain pressure. Aside from the essential and objective features of this case, namely, the change in size and shape of the upper part of the head, there are other equally distinct features to which your attention must now be directed, and these are for the most part compression symptoms, the brain being actually compressed within the child's skull by the amount of fluid already present. You must not forget that the evidences of brain pressure are invariably the same, no matter what the compressing causes may be. These are unconsciousness, paralysis, loss of special senses, etc. In this instance the child remains for the most part apathetic, pays no attention to its surroundings, to flashes of light, nor to bright colors, is not attracted by moving objects, nor seriously moved by anything save that which gives acute pain. This night of the senses is characteristic of all these causes. The especial sense last to be affected is that of hearing, largely because of the great protection afforded to the organs of audition.

Regard now, for a moment, the hydrostatics of the craniospinal canal. You know that when fluid is confined under pressure, this pressure is equal at all points. Now the ventricles, the subdural space, the subarachnoid space, and the spinal canal all connect through well-known anatomical paths. The greater part of this fluid is normally contained within the subarachnoid space, which ordinarily is scarcely recognizable over the convexity of the brain, but easily so at the base, forming there the so-called "water-bed" upon which the brain is regarded as resting. This space connects with the ventricles by the foramen of Magendie, as well as with the sheaths of the nerves, from the orbit to the lower part of the spine. Pressure upon these nerves must interfere more or less with their function, evidences of such pressure being particularly distinct when made along the optic nerves. It is through the meshes of the arachnoid that the subdural and the subarachnoid spaces communicate. Thus, you will say that closure of Magendie's foramen may lead to the internal form of hydrocephalus. The subarachnoid space extends down the spinal canal; therefore, if it be tapped at any point the fluid will be removed from the cranial cavity.

Now the whole surgical treatment of hydrocephalus, consisting in removal of the excess of fluid, or at least of some part of it, is an affair mainly of deciding how this may best be effected, and whether it shall be a single or an occasional tapping, or a continuous drainage. The former is less serious and easier done, but correspondingly less efficient. Drainage when once established can be made efficient *if septic infection can be prevented;* this, however, is an almost impossible task, especially in little children or in babes like this one, and for reasons which are so self-evident that I need not discuss them here, this being equally true of drainage either about the head, neck, or lower spine. We have essentially the following methods, then, from which to select: (1) Tapping or drainage of the lateral ventricles. (2) Tapping or drainage at the base of the skull. (3) Tapping or drainage in the lumbar or lumbosacral region.

Some time ago I illustrated in this clinic the method of draining the lateral ventricle, in an infant some months older than this one, with a much expanded head. I made a small trephine opening at a point about an inch behind the external meatus and a little more than that above the base line of the skull; here I inserted a small trocar in a direction toward the opposite parietal eminence until it entered the lateral ventricle, which was drained by a very small rubber tube. In this instance I took strenuous pains toward asepsis and when the child died, as it did some two or three weeks later of marasmus, it was found both on ordinary examination and by culture experiment that there was an absolute freedom of the interior of the cranium from all septic infection. This method has been resorted to a number of times but has rarely if ever given anything like permanent satisfactory results. However, the ventricles when distended thus may be attacked either for effusion of blood, for acute distention by serum, for a collection of pus, for effusion due to pressure, for brain tumors, and for the diseased condition now under consideration. Not the least of the difficulties in the case is that met with in connection with the fluid which constantly escapes into dressings in which it may decompose and thus permit of infection. In time past a few surgeons have had the hardihood to inject a weak solution of iodin after withdrawal of some intracranial fluid, and though I have read of a few instances in which it was done with impunity there are no records to show just how often it has been fatal, though certainly this has been the case in a majority of instances.

Basal Drainage.—In 1893 Parkin suggested trephining of the occipital bone and puncturing of the subarachnoid space; and of five cases treated in this fashion, one of them being a case of tuberculous meningitis, three recovered. In the same year Stephen Paget thought to drain a case of acute meningitis by cutting away the posterior arches of two cervical vertebræ, the fourth and fifth, and although he opened the membranes, the autopsy showed that the drainage was insufficient, and that occipital attack would have been more successful. Drainage at the base of the skull, combined with pressure, has been even more successful. One foreign surgeon made three punctures in a four-months' old baby, and removed altogether 1135 cubic centimeters (more than two pints) of fluid, but improvement was only temporary. Baskett, a British surgeon, operated on a child nine weeks old, tapping the head and removing a half pint of fluid, and a few days later he incised the anterior fontanel, with temporary improvement. The opening between the ventricles closed, after an attempt was made to relieve pressure by an opening on the other side, and the autopsy revealed a plug of pus in the dilated foramen of Monro. And so the matter stands with regard to surgical operations upon the head for hydrocephalus. If this route be adopted, I should advise the insertion of some aid to continuous drainage, as, for instance, a bundle of prepared horsehair introduced through Horsley's dilating director. Not infrequently we have, as a result of tapping, signs of cerebral irritation; *e.g.*, vomiting, cramps, crying, pyrexia, etc. Since puncture, frequently repeated, is hazardous, I hold it good practice to make two or three punctures at most, after which, if marked improvement does not occur, it is best either to discontinue them or to establish permanent drainage.

Spinal Drainage.—Thirdly, we have to discuss the question of attack through the lumbar or lumbosacral region. In 1891 Wynter suggested drainage through the lumbar region by puncture of the membranes. After tapping a three-year-old patient, he maintained permanent drainage by a rubber tube. Much improvement followed for a time, but when the fluid ceased to escape the child died. About the same time Quincke reported ten operations, pressure upon the skull being combined with puncture in the lower spinal region. One of his patients was cured, in three there was considerable improvement, and none of them died. The suggestion to merely puncture has been modified by some who have cut down upon the lumbar vertebræ and either punctured the dural membrane, or, in at least one instance, opened the spinal theca and stitched its edges to those of the skin wound. These more radical measures have never succeeded in giving permanent relief; on the other hand, the method of simple puncture, which I shall illustrate in this case, has been followed in some cases by the best results. According to the last statistics, Quincke has done the operation forty-one times, and values it, not alone for its therapeutic affect, but because of its diagnostic possibilities, since the fluid thus obtained may be submitted to both chemical and microscopic analysis. When the albumen increases beyond the proportion of one part to 1000 there is an acute increase in the degree of inflammation and exudation present; should the fluid be bloody this is still more true.

Next let me call your attention to the anatomical fact that the spinal cord, as such, terminates opposite the second lumbar vertebra, and that a needle point introduced at the lumbosacral junction cannot, at most, do more than injure some particular nerve trunk. There are two or three methods by which this little operation may be performed. In infants the cauda equina is divided into two lateral bundles, separated by a space of half a centimeter, and the distance from the exterior to the cavity of the spinal canal, in infants, is two centimeters, or a trifle more, while in adults it is two or three times that distance. As you see, I make use of an ordinary aspirating needle, which may be passed in quite obliquely toward the interior, between the third and fourth lumbar vertebræ, or at the same level by piercing the skin perpendicularly a little to one side of the middle line; or, the lumbosacro interval may be perforated, after the latter fashion, the needle being directed a little more obliquely, which plan I shall follow in this case. I expect to direct the point of the needle upward and forward through the latter space, because it is larger, and the danger of injury to the nerves is decreased.

I have had a little ether administered so that the baby may not suffer, though it is likely that I could perform the operation in its present mental condition without provoking much evidence of pain. I place the child over the end of the table, with its buttocks projecting, and its legs hanging down, in order to curve the spine and open the lumbosacral space as widely as possible. The skin has been carefully prepared, as has this needle, which has just been taken from boiling water. Entering the needle a little to one side of the middle line I pass it forward in a direction slightly upward, which I know must take it into the spinal canal at a depth of about

2 centimeters. You see that the fluid begins to flow out and so easily that I disconnect the suction apparatus and simply let it escape as it will. Observe now a very interesting phenomenon. The child having partially recovered from the effect of the anesthetic, every time it gasps, or cries, or coughs, we see that the stream of fluid becomes a jet which is spurted out to a little distance. This should remind you that with every expiratory effort blood is forced into the cavity of the cranium and tends to expel the cerebrospinal fluid contained therein. I could give you no better demonstration of what I before alluded to as the law of hydrostatics within the cerebrospinal canal. This is the legitimate but secondary outcome of a scientific surgical operation for the relief of this condition. In this way I permit as much fluid to escape as runs easily, and now that it comes drop by drop I withdraw the needle, make pressure over the opening, seal it with collodion, and over this apply an aseptic dressing.

NOTE.—The child was shown to the class on the fourth day with the mother's statement to the effect that it had seemed less listless and more active than before the operation, while at the same time it had been more irritable and called for more attention on her part. The patient was dismissed with directions to the parent to report for a second puncture at the end of one month. At the expiration of the month the child was again shown to the class. Its condition was certainly improved; it was brighter, noticed things about it, and made ordinary motions with its limbs. The anterior fontanel did not bulge, and there were no signs of increased pressure within.

MEDICAL PROGRESS.

The Probable Cause of a Typhoid Epidemic.—BERRY (*Lancet*, December, 1896) reports the details of an epidemic of typhoid fever which occurred in Grantham during the summer of 1896. No explanation of its origin was obtained by an examination of the water supply, of the milk and food supply, of the sewers of the district, or in the disposal of excrement. A careful study of the history of the epidemic led the writer to believe that the poison was introduced into the subsoil from a block closet in an early case, and that it was disseminated either by ground air or by ground water. This view is supported by the fact that the point where the epidemic commenced is higher than the districts subsequently affected. Further, the sudden cessation of the epidemic (allowing for the incubation period of the disease) coincided exactly with the falling of cold rains, which would check germ growth in the affected subsoil.

Consideration of the Modern Treatment of Hypertrophy of of the Prostate from an Experimental Point of View.—In view of the widespread popularity of double castration for hypertrophy of the prostate, the results of Sackur's experiments on dogs and rabbits are of interest. In examining the preparations of contracted prostates, Sackur came to the conclusion that the process is not one of proliferation of the gland cells, then fatty degeneration, and finally disappearance of these cells, nor is the process one of hyperplasia, but is rather an embryonic connective-tissue production rich in the proliferation of cells encompassing the individual acini, which compress the lumen of the glands till these finally atrophy and disappear altogether. The increase in the interacinous tissue is only a relative one, brought about by the disappearance of the glandular tissue. Hence the truth of the assertions of those authors who ascribe better results in those cases where castration was performed for soft hypertrophy of the prostate than in the cases of hard hypertrophy. In the former, there was a great deal of glandular tissue that could undergo atrophy, which could not take place where the hypertrophy was of a fibrous nature.

Sackur further demonstrated experimentally that the removal of but one testicle has but little effect on the reduction of the hypertrophy. In such instances hypertrophy of the remaining testicle takes place. He was able, by section of both vasa deferentia or resection of the same, to obtain complete results. In one case, however, in which no result was obtained, the author could detect a delicate canal which served to connect the severed ends. Section of the nerves of the testicle was followed by the same results as castration. This latter method is precluded in human subjects by the difficulty of the technic. Gangrene of the testicles did not follow either complete section of the vasa deferentia or section of the nerves. Collating the experimental and clinical results, Sackur arrives at the following conclusions: (1) Instead of castration, ligation and section of the vasa deferentia in toto and resection of the isolated vas give equally good results in cases of hypertrophied prostate. (2) Cessation of the testicular function is indispensable to a cure. Single castration is of no avail.

The Ability of Bacteria to Pass Through Intestinal Mucous Membrane.—The question of the permeability of the intestinal canal for different kinds of microorganisms has been revived by the investigations of French authors, who claim to have found bacteria in great quantities in the chyle. NEISSER, however (*Centralbl. f. innere Med.*, No. 50, 1896), claims that the chyle, under ordinary circumstances, is entirely free from bacteria, and, although it does not possess any germicidal properties, he did not find any bacteria either in the lymph glands or in the blood vessels associated with the intestines; so he concluded that the intestinal wall was not pervious to them. Nevertheless, the question is not entirely settled, for there seem to be circumstances under which bacteria in the intestines are capable of setting up a general infection, while under other circumstances, countless germs of a highly pathogenic character may remain for days in the intestines without doing any injury.

The Diagnostic Value of Dental Malformations in Hereditary Syphilis.—FORTIN (*Gazette Hebdom. de Med. et de Chir.*, No. 96, p. 1149) considers these dental dystrophies more important in the second than the first dentition, though observed in both, and enumerates:

1. Early alterations: Slow eruption, erosions, micro-

dentism, amorphism, softness of the dental system, white ridges, and irregularities of implantation.

2. Secondary alterations: Changes of color, accumulation of tartar, traumatic lesions, caries, stomatitis, and early loss of teeth.

Collectively, these malformations indicate only a nutritive disorder, or an arrested development, and, considered individually, no single one is pathognomonic of hereditary syphilis. Erosions are seen in children who have had convulsions, in the scrofulous, in chronic enteritis, and in idiots. The notching of the superior lateral incisiors (Hutchinson), very rare without syphilitic history, is nevertheless seen in the scrofulous.

Tentative treatment is advised in every case of hypodermic injections of mercury and iodid of potassium, care being taken to avoid mercurial stomatitis.

Dental malformation may be hereditary.

THERAPEUTIC NOTES.

Influence of Vapor Baths Upon the Blood Pressure.—CERRINA (*Bull. Gen. de Therp.*, January 15, 1897) has conducted a series of experiments in order to determine whether vapor baths can be prescribed without danger in the diseases which affect the circulatory system. He finds that without exception vapor baths reduce the blood pressure. The indications for their use are given by him as follows:

1. In those affections accompanied by increased blood pressure (aortic insufficiency) vapor baths are of service in reducing this pressure.

2. In those conditions which predispose to apoplexy vapor baths are not contraindicated. Indeed, owing to the cerebral anemia which they produce, such baths may act to prevent an apoplectic stroke.

3. In cardiac affections with diminished blood pressure (mitral lesions) a distinction must be made between cases with complete compensation, and those in which compensation is incomplete. In the former cases vapor baths may be used as the diminution of pressure thereby produced is not greater than the diminution which occurs after such baths in health. In uncompensated cases vapor baths are absolutely contraindicated.

Comparative Therapeutic Value of Active and Passive Exercise.—SEAVER (*Yale Medical Journal*, March, 1897) concludes an interesting study of the effects of active and passive exercise upon the different systems of the body with the statement that passive movements produce less active, but more complete combustion, and the waste products are in better form for elimination than under more rapid waste production of active exercise. Moreover, there is undoubtedly a possibility of securing a healthful exercise of central nerve-cells by peripheral manipulation.

However, it appears that passive exercise cannot take the place of active exercise in the relief of what may be considered over-charged motor areas in the brain, and that its highest use will be found in such cases of malnutrition and cell exhaustion as occur when debility is the result of overwork and prolonged wear and tear. It would, therefore, be preposterous to prescribe passive exercise for a person whose central nervous system was irritable from lack of normal discharge of nerve force, and active exercise would be strongly indicated. A converse of this statement is also true, that to prescribe active exercise for a person whose motor areas are all overworked, or whose nutrient processes are poor, would be prejudicial to the future health of the patient. It should then be borne in mind when considering the practicability of prescribing exercise that an intelligent choice should be made, as in the use of ordinary drugs; for in no other way can we expect to obtain uniform and satisfactory results.

Treatment of Tuberculosis of the Larynx.—Since lactic acid was first recommended for the treatment of tuberculosis of the larynx it has been widely employed on account of its property of attacking only the diseased tissue. BOTEY in order to avoid the severe irritation, with laryngeal spasms which sometimes follows its use, recommends (*Centralbl. für die Gesam. Ther.*, January, 1897) a combination of lactic acid with carbolic acid and glycerin, which possesses, according to his experience, the quieting action of the latter substances with the specific action of the former. He begins with a solution in glycerin of carbolic acid five per cent., and of lactic acid ten per cent. In sensitive patients the use of cocain is advisable. The brush should be introduced three or four times and an energetic application made. The strength of the solution may be rapidly increased until the following is used: Carbolic acid one part, lactic acid three parts, glycerin four parts.

Radical Cure of Hernia by Implanting a Section of a Sterilized Sponge.—In the *Bulletin* of the Johns Hopkins Hospital, March, 1897, PLATT describes an operation which he has four times performed for the radical cure of inguinal hernia. The canal is laid freely open. The sac is opened, emptied of its contents, ligated as high up as possible, and removed. A piece of fine, firm sponge the size, shape, and thickness of a silver dollar is sterilized without boiling by immersion in soda solution, sterilized water, permanganate of potash, oxalic acid, and normal salt solution. A radial incision is made in the sponge and it is slipped over the cord. The edges of the cut in the sponge are slightly overlapped and held together by two sutures. The disk of sponge is then spread beneath the abdominal ring at right angles to the cord which pierces its center. The conjoined tendon is then sutured to Poupart's ligament by two or more quilted sutures. The inguinal canal is closed with silk, and the skin with silkworm gut. "It is absolutely necessary to use some kind of drainage in the upper part of the wound, as there is invariably some serous oozing and swelling. This may be removed after twenty-four hours." Platt has performed this operation upon four children, aged four, five, eight, and twelve years. In two of the cases it was necessary to remove the deep sutures on account of a persistent sinus which healed without the removal of the sponge. One of these cases recurred in five months. The other cases were well seven months after operation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, APRIL 3, 1897.

EXACTNESS IN INFANT FEEDING.

IN this issue will be found a mature article on the subject of modified milk, by the originator of this plan of substitute feeding. Prof. Rotch has taught the profession to think in percentages, to feed by figures. Many excellent preparers of adult foods, with a little of this and a pinch of that, set upon the table triumphs of individual skill. It is a notable fact that such masters of the art cannot, as a rule, impart to others their recipe and secure to them like results. Feeding by prescription, estimating by percentages, thinking in figures, an intelligent mutual understanding among physicians—these are some of the features of this exact method.

There have been three important steps in exact infant feeding. The first came from studying the composition of the breast-milk of women nursing infants of equal age, all thriving. It was found that the component parts of such feedings vary greatly (Rotch, Adriance). Disturbances of mind and metabolism, worry and fatigue, influence the milk composition. If a mother worries, the baby has colic; if she gets overtired shopping, a like result. If a stolid wet-nurse sits indoors and gets constipated, the baby is affected. It is now known that this disturbance is due to a derangement of the proper proportions of the constituents of the milk.

The first step consisted in ascertaining the low and high average percentages of fat, sugar, and proteids in the breast-milk of women nursing thriving infants, when once rapid growth had been established. Such percentages have been found to be, approximately, low average: fat, three per cent.; sugar, six per cent.; proteids, one per cent.; high average: fat, four per cent.; sugar, seven per cent.; proteids, two per cent. In earliest infant life, when there is no breast-feeding, there is a departure from these standards, likewise in normal conditions of the infant's digestive capabilities.

The second step consisted, after having learned the variations of breast-milk, in procuring a substitute feeding capable of equal variation. Practically, cow's milk is the only substitute for mother's milk. At the outset, the problem has been to convert the percentages—fat, 4 per cent.; sugar, 4.5 per cent.; proteids, 4 per cent.—to the above-mentioned high and low average percentages of breast-milk. Dr. Rotch has studied the first and second steps in a masterful manner. He has studied Nature's variations, and has thereto adapted substitute variations:

Low average—Fat, 3 per cent.; sugar, 6 per cent.; proteids, 1 per cent.
High average—Fat, 4 per cent.; sugar, 7 per cent.; proteids, 2 per cent.
Cow's milk—Fat, 4 per cent.; sugar, 4.5 per cent.; proteids, 4 per cent.

His aim has been to take cow's milk apart and put it together in the proportions of breast-milk, to add lime water to tip the balance from acid to alkaline, heating it enough to insure its freedom from pathogenic germs. He does not put into the milk cane-sugar; he does not put into it cereals; he does not put into it patent prepared commercial foods. With his eyes upon Nature's lines of variation, he prescribes a varied substitute.

The third step consisted in making it possible to adapt this study to practical purposes. Prescription writing, laboratory compounding, exact dosing, is as fruitful of good results in feeding as in pharmacy. It is everywhere evident in the writing of Dr. Rotch that the study of infant feeding, for which he will always be known, has begun with the dairy and continued to the nursery. Clean cows and clean stables, clean milkers and clean pails, rapid cooling and quick transportation have been emphasized. Good milk, carefully handled, exactly modified, and intelligently prescribed—this is the accomplished work, which future writers will dwell upon with unstinted praise.

In pediatrics there is nothing more important than feeding. In feeding there is no method comparable with that of modified milk. The graduate of fifteen-years' standing has seen added to pediatric practice three great aids: intubation, antitoxin, and exactness in infant feeding.

THE MODERN TRAINED NURSE.

Both lay and medical British journals have, of late, discussed the modern trained nurse from a sociological and professional standpoint. The chief lay critic, Lady Priestley, denounces the private nurse as "arrogant, dictatorial, flighty, frivolous, overtrained, underbred, an *intrigante* of the first water, a matrimonial adventuress, and an expensive luxury of doubtful utility." An English opinion on this subject demands some respect, as it was in Great Britain that the trained nurse was first evolved. It cannot be denied moreover that some of the painful experiences of Lady Priestley have been ours, and a short discussion of the subject is therefore not out of place.

Whatever faults or shortcomings a trained nurse may have, we may rest assured that the factors governing her selection, training, and after-management are largely responsible. The semiprofessional nature of the occupation imparts a sort of glamor which attracts more than the compensation and, it must be confessed, the class thus attracted seldom make the most desirable nurses. Feeling themselves too good for domestic service or employment in factory or shop, they see in nursing a sphere of intimate usefulness where indulgence, more than desert, has accorded them a social status to which some condescend to let themselves down, and to which others rise with undisguised satisfaction. That this anomalous, and often undeserved social standing, is sometimes taken advantage of is true. Too many immature women are admitted to training schools, and too many with unchangeable and improper ideas of the position and functions of a nurse. Once admitted, the period of probation is too short and the weeding-out process during, and at the close of this period, is too restricted. The curricula of most schools are too theoretical. Courses of study and lectures, on subjects better left alone, consume time and strength which should be devoted to practical work. This is partly the physician's fault, as he it is who lectures too frequently "over the nurses' heads." Often, however, the managers, or the principal, map out the lectures, which frequently are as inappropriate in training schools for nurses as conic sections in a kindergarten.

Again, in undergraduate life too much is made of the supposed hardships of nurses, and they are entertained, coddled, and housed in palatial quarters until thoroughly spoiled for their real life-work. Treated often with more consideration and quartered more sumptuously than the house staff, whose servants they are, what wonder that they sometimes become "arrogant" and "dictatorial," as Lady Priestley says, when graduated and free lances in the community.

If judiciously selected and properly trained, the modern nurse is an unmixed blessing. Faithful to patient and loyal to physician, how much suffering she saves one, and how much anxiety the other! "Flighty," "frivolous," or "underbred" they never could be if properly selected; "arrogant," "dictatorial," or "overtrained" they never would be if properly taught; and, if they sometimes stoop to "intrigue" or "matrimonial adventure," who dare deny that the physician sometimes sets them the example.

Having nothing to do with the admission of nurses to training schools and little to do with their instruction, the profession has to take them as they are; but it lies in the power of physicians by firm and concerted action to keep an undesirable nurse out of employment, and in that way save the public or profession from her blighting presence. The selection or retention of a nurse generally devolves upon the physician, and he has himself to blame if a nurse, found to be disloyal to him or unfaithful to his patient, continues to prosper.

What is really a fact to be deprecated is that overproduction and a predilection on the part of some employers and physicians for the young, fresh, and pretty, have crowded the older, more experienced, and hence, really more desirable nurses out of private employment. This deplorable condition has not proved an unmixed evil, however, for, while those of the profession who appreciate faithfulness and experience in a nurse rather than youth and comeliness, have lost trusty helpers, the poor have been gainers, as many of these veterans have taken up district nursing, in which occupation they get a small regular salary and do an immense amount of good among the poor, not only ministering to their physical ills, but also doing invaluable missionary work in matters of cleanliness and hygiene.

With all her virtues and all her faults, we must remember that the trained nurse is a woman, and that the lines of Scott apply to her as well as to the rest ot her sex:

> “When pain and anguish wring the brow,
> A ministering angel thou!”

THE CANADIAN MEETING OF THE BRITISH MEDICAL ASSOCIATION.

“POLITELY but firmly,” says the *Medical Press*, “measures are being taken to point out that the meeting of the British Medical Association at Montreal, in August next, is not intended for the *‘οι πολλοι* of the American profession of the United States, but that it is distinctly a gathering of the members of the Association, together with certain specially invited guests.”

There can be no reasonable objection to the Association making such arrangements as will best conduce to the success of the meeting in accordance with its highest objects and aims, but it is just possible that this can be more “politely” done than has been attempted in this brusk venture of our excellent contemporary. However, it is important that the members of the profession should comprehend the circumstances under which the Association meets this year in Montreal, and so avoid any embarrassment or irritation that might arise from misunderstanding.

> “We're a great people, that's beyond a doubt,
> And nothing loth to let the secret out.”

The officers of the British Association have evidently heard of it, and have also learned that the American profession believe in the benefits derived from an interchange of ideas and experiences and have a commendable proclivity for attending medical meetings for that purpose. They are evidently afraid, and perhaps justly so, that they will be completely swamped at Montreal by the American contingent.

The committee of honorary local secretaries has candidly set forth the situation in a communication to the *Medical Record*. In this the committee points out the fact that it is doing all in its power to have as many friends present as can safely be invited. Not more than a few hundred Old-country members can possibly be expected, Canada with her sparce population will be represented by hundreds not thousands, and the other British colonies and dependencies by a limited number of delegates; “and were we to throw the meeting open to the medical men in attendance upon the sixty-six million inhabitants of the United States, the whole character of the meeting would be destroyed—it would no longer be a meeting of the British Medical Association, but would assume the nature of an American medical congress with British officeholders.”

For the British Medical Association to be so completely swallowed up the first time it ventures out of the confines of its sacred dominions would be sad indeed. If, however, it be true that many practitioners, especially in the West, were intending to neglect the meeting of the American Medical Association in Philadelphia, reserving their time and money for a trip to Montreal, the danger was imminent, and they do wisely to anticipate it. With the meeting of the Congress of American Physicians and Surgeons at Washington in May, and that of the American Medical Association at Philadelphia in June, sufficient opportunity will be afforded this season for indulgence in the American proclivity and for the craving for scientific pabulum to be amply satisfied. We heartily endorse the suggestion of the *Record* when it says: “We sincerely hope that no American will be seen in Montreal at the meeting of the Association who does not go as an official delegate from some society empowered to send him, or in response to a personal invitation from some one in authority.”

ECHOES AND NEWS.

Dr. T. A. Emmet Honored.—The Council of the College of Notre Dame, at South Bend, Ind., has conferred on Dr. Thomas Addis Emmet of New York the Laetare medal. This is in accordance with the annual custom of the institution to do honor to some eminent American Roman Catholic.

Antitoxin—American Pediatric Society.—The collective investigation (report) will be kept open until April 10th, in order to secure returns of all cases beginning before April 1st. The committee desires to express its appreciation of the trouble and pains the profession has been willing to take in this matter. The return blanks have been more complete and accurate than in the first report.

The New York County Society on Compulsory Reports of Phthisis.—This society, at its recent meeting, rejected the report of its committee sustaining the action of the Board of Health, and adopted the following: Resolved, that in the judgment of this society, the recent edict of the Health Department in relation to the compulsory reporting of cases of tuberculosis is unnecessary, inexpedient, and unwise.

Opening of the New Lecture Room of the Boston Infants' Hospital.—On March 17, 1897, Dr. W. P. Northrup, Professor of Children's Diseases in the Bellevue Medical College of New York, addressed, by invitation, the students of the Harvard Medical School on "Tuberculosis in Children." The lecture was illustrated by lantern slides. It was a great success, and excited much interest.

Corsets Abandoned.—The latest exploit with the Röntgen rays is reported from Lisbon. It was at the instance of the Queen of Portugal, who takes a keen interest in science, that the ladies of her court submitted themselves to the searching action of these vibrations. The ladies have been startled at the sight of their distorted ribs and bones, the result of tight lacing. Henceforth they have determined to be free women. Corsets are to be cast aside.

A Barbarian Notion of Sanitation.—The natives of the village of Ixtlan, Mex., have taken a genuine Indian method of stopping the spread of smallpox, which appeared in that town. The first man to take the disease was the alcalde of the pueblo, and the Indians concluded that the place to stop it was at the fountainhead. They appointed executioners, who went to the house of the alcalde and beat him to death, and then set fire to the house and burned it and everything that was in it, including the body of the murdered man.

Hospital Shaken by an Earthquake.—Shortly after midnight on March 27th Montreal was visited by a startling earthquake, the second within the week. Its force was thought to have been especially great in the vicinity of the Notre Dame Hospital. The chimney-caps were thrown to the sidewalk and the walls of the building severely agitated. The inmates were greatly demoralized by the shock which aroused them suddenly from their slumbers, and order was with difficulty restored by the sisters and house-staff.

Fanaticism in Bombay.—One of the London daily papers prints a despatch from Bombay, which says that the fanatical Mohammedans there display the bitterest opposition to the measures taken by the government for suppressing the bubonic plague. For instance, a Mohammedan, while leaving the city with his wife, refused to allow her to submit herself to the prescribed inspection. The officials insisted, whereupon the Mohammedan suddenly drew his dagger and stabbed her to the heart. Then he stabbed the official physician and attempted to kill himself.

The Widal Agglutination Test for Typhoid Fever.—Dr. Wyatt Johnston recently stated that in the application of this test to more than six hundred cases his confidence in its reliability had not been in any degree diminished. The peculiar reaction was occasionally delayed until the fifth day, and in rare instances would disappear after the fifteenth day. Certain somewhat similar reaction had also been observed from the blood of patients ill of other diseases, but a little experience should enable the careful observer to recognize the characteristics of the typhoid reaction from any of these.

The Bald Man's Bacillus.—Dr. Sabourand has reported to the Dermatological Society of Paris that premature baldness is chiefly due to the ravages of a bacillus which takes up its abode in the fatty cells lying about the roots of the hair. Whether this parasite consumes the nutriment provided by nature for the support of the capillary crop or secretes a "toxin" that is fatal to the hirsute growth seems to be as yet undecided. The eminent physiologist has succeeded in cultivating the creature after the most approved Pasteurian methods, and a sheep inoculated with the virus showed bare patches of a most gratifying nature. The next step will be to develop an antitoxic serum and immunize the descendants of the occupants of the "baldheaded row."

Guilty of Having "Knock-out" Drops.—Charles Guichard, a jeweler's apprentice, was convicted in General Sessions March 24th of having "knock-out" drops in his possession. It was the first conviction under the law passed March 9 making it a felony for any person other than a regularly licensed physician to have poisonous or anesthetic drugs in his possession. Guichard's offense was committed March 11. He went to a drug store in Bleecker street and offered the clerk $15 for some hydrate of chloral, vulgarly known as "knock-out" drops. The clerk told him to come back later, and in the meantime notified the police, who waited until Guichard had put the mixture in his pocket, and then arrested him. Guichard's defense was that he had bought the drug for a woman, who offered him $50 for it. The maximum penalty for the crime is ten years in State prison.

Hygienic Measures Before the New York Legislature.—The committee on public health has under consideration a bill prohibiting the cutting of ice for any purpose within one thousand feet of the outlet of any sewer, or within or opposite the corporation limits of any city or town having over fifty thousand inhabitants. The committee on ways and means is considering a bill requiring that every building or room occupied as a butcher's shop, meat market, or fish market, or in which meat or fish intended to be used for food is exposed for sale or stored, shall be under the jurisdiction and subject to the inspection of the factory inspector, or a deputy factory inspector duly authorized by him. The factory inspector may adopt such rules and regulations in relation to the construction, ventilation, drainage, plumbing, and maintenance of such buildings or rooms as he deems necessary to secure the healthful, cleanly, and sanitary condition thereof.

Obituary.—Dr. Douglas Ewell died on March 24th, in his apartments, in New York. He was thirty years old and unmarried. He was born in New York, and was demonstrator of anatomy at the College of Physicians and Surgeons. He was also connected with Roosevelt Hospital.—Dr. Thomas Scott Lambert of New York, who died last Sunday at Stamford, Conn., was widely known several years ago as a writer and lecturer on educational and physiological topics. "Lambert's Anatomy" was a text-book in the public schools of various large cities between thirty and forty years ago. Dr. Lambert was born near Boston, Mass., on May 22, 1819; was educated at Williams College, and took his degree in medicine at Castleton, Vt. He became a specialist in anatomy and physiology, and spent the greater part of his life in lecturing on those subjects. He published his text-book on anatomy about forty-five years ago, and in recent years he undertook to revise that work, but his mental faculties became impaired by overwork, and he spent the latter part of his life in a quiet retreat in Stamford.

Antitoxin of the Bubonic Plague.—Dr. A. H. Doty, Health Officer of this port, assisted by Dr. T. D. Fitzpatrick, has been experimenting to discover an antitoxin for the bubonic plague, and recently made a report to the New York Health Board. In the report he says: "On February 26 a horse was inoculated with a culture of plague bacillus. This was repeated on March 4 and 9. In order to determine how early the serum might have acquired antitoxic qualities, about a pint of blood was drawn from the horse on March 15 for experimental purposes. From this, one-half a pint of serum was secured. Several white mice were each injected with one cubic centimeter. After thirteen hours they were inoculated with a culture of the plague bacillus. These all remained alive. Several into which serum was not injected, when thus inoculated, died, showing the efficiency of the serum in the cases of those that lived. These results would indicate that the serum in this horse will surely be both preventive and curative."

The Medical Buckeye Flyer.—Arrangements have been made for a special train, which will be known as the "Medical Buckeye Flyer," which will be made up of Pullman palace cars, for the accommodation of those who cannot conveniently reach the *Journal* Special on account of the locality in which they live. This train will go via Columbus, Ohio, where it will be joined by many of the military surgeons, who hold their annual meeting in that city just prior to the meeting of the American Medical Association. It will be a through train, without change of cars, to Philadelphia, over a route both picturesque and historic. Reduced rates will be made and the best of accommodations provided, care being taken with regard to the comfort of the passengers in avoiding overcrowding of cars. Stop-over privileges at Washington have been arranged for without extra charge. Those who desire to take this train will receive further information by addressing DR. R. HARVEY REED, Columbus, Ohio.

The New York Academy of Medicine and the Control of Tuberculosis.—The committee appointed by the Academy of Medicine to consider the question of the control of tuberculosis presented its report, which was adopted, as follows: (1) In the opinion of this committee, the Board of Health might wisely delay the enforcement of compulsory notification, but should adopt more stringent measures for the care of sputum in factories, workshops, tenement-houses, ferry-boats, places of public assemblage, and public conveyances. (2) The establishment and maintenance by the city of a hospital or hospitals, to which indigent tuberculous patients may be admitted, is advisable. (3) This committee recommends the appointment by the Legislature of a commission for the establishment and management of sanatoria in healthy country districts in this State for the care of the indigent tuberculous patients in the early stage of the disease. (4) This committee commends to the State Board of Health the importance of the careful regulation of the sanitary condition of hotels and sleeping-cars throughout the State. E. G. JANEWAY, M.D., Chairman; T. MITCHELL PRUDDEN, M.D., Secretary.

New York School Physicians and School Inspectors.—Some confusion has arisen in medical circles in regard to these two classes of public servants. The positions and duties are entirely distinct. The duty of the inspectors, of whom there are one hundred and fifty, is to visit their respective schools at nine o'clock every morning during the session. Upon assembling in the morning, every child that appears ill, or who presents himself for the first time after being absent, is sent to a special room, where he is inspected. If found attacked by an infectious or contagious disease, or not fully recovered from one, the inspector sends him home, with a note to that effect, and at the same time informs the Board of Health of the fact. The salary of the school inspector is thirty dollars per month. The duty of the physicians, of whom there are ten, is to examine all applicants for positions as teachers in the public schools. Like the police and fire departments, the Board of Education requires of all applicants for positions on the teaching staff a certificate from one of the school physicians attesting to the physical soundness of the applicant. The following have been appointed school physicians for the year 1897: W. Gill Wylie, Samuel M. Brickner, John G. Truax, P. J. Lynch, Josephine Walter, John Rogers, Jr., Clement Cleveland, Matthias Nicoll, Jr., Alexander Lambert, A. M. Jacobus. The fee for each examination is $3.

Dr. Koch's Rinderpest Cure.—In his recent report to the Department of Agriculture, Dr. Koch says that the blood serum of cattle which have recovered from rinderpest has a certain immuning effect upon healthy stock when inoculated with it. Its protective properties, however, are not very great, for 100 cubic centimeters of such serum are required to protect an animal against an inoculation with a small dose of rinderpest blood. This immunity is in its nature merely a "passive" one, and will only last during a short period. "For protective inoculation on a large scale such serum is not applicable, but I succeeded in immuning within a fortnight several animals by means of a mixture of serum and virulent rinderpest blood to such a degree that they were enabled to withstand an injection of twenty cubic centimeters of rinderpest blood, a ten-thousandth part of which is a fatal dose. A second and equally important fact is that one is able to render immune healthy cattle with the bile of such as have succumbed to rinderpest. In this case, only one hypodermic injection of ten cubic centimeters is sufficient. This immunity sets in on the tenth day at latest, and is to such an extent that even four weeks afterward forty cubic centimeters of rinderpest blood could be injected without any injurious effect. I therefore conclude that the immunity produced in such a manner is of an "active" nature. The local result of an injection is merely a hard, somewhat painful swelling of the size of a man's fist, which gradually disappears in the course of a few weeks, provided, however, that the bile is not in a state of decomposition, as is not uncommon when an animal suffers from rinderpest."

The Regulation and Control of Dispensaries.—The following bill has been introduced in the New York Legislature:

"Section 1. A 'dispensary' is hereby defined to be a place, established by any person, persons, or corporation, for the practice of medicine and surgery, and to give medical and surgical aid or treatment gratuitously to poor persons who are unable to pay therefor.

"Sec. 2. No person shall apply for such treatment in any dispensary, nor shall any person, persons, or corporation conducting such dispensary, give treatment or medical aid to any person, unless such person so applying for such treatment shall be a poor person and unable to pay for medical treatment; and all persons who are entitled to be so treated shall be treated by such dispensary free from charge for services so rendered, and shall be furnished with the necessary medicines or appliances required by such treatment.

"Sec. 3. In no case shall any person, persons, or corporation conducting such dispensary, directly or indirectly receive any pay or compensation whatever for the treatment of any such persons entitled to be so treated, nor be entitled to or receive any pay or compensation for the medicines or appliances so furnished, and no person who is not a poor person shall be so treated in such dispensary, except in cases of emergency.

"Sec. 4. No dispensary shall be carried on or conducted in any place, commonly known as a drug store or a place for the sale of drugs or medicines, nor shall the same be carried on in any place commonly known or defined by law or by the rules and regulations of any health board or health department as a "tenement-house."

"Sec. 5. All persons desiring to avail themselves of the right to be so treated in any such dispensary shall produce to the person, persons, or corporation so carrying on said dispensary a certificate in writing from the owner or owners of the premises wherein said person resides, or from the police captain or person in charge of the police district or precinct in which he or she resides, or from the alderman of the district, or from any charity organization, that the said applicant is a poor person, unable to pay for medical treatment or medicines; and such writing shall be in the form prescribed by such dispensary, and be of no force and effect after the expiration of thirty days from the date thereof.

"Sec. 6. Any person who shall apply to such dispensary to be treated who is not a poor person, or shall obtain treatment or medical aid at such dispensary when he or she shall not be entitled thereto under the provisions of this act, the person so applying or so receiving such treatment or medical aid, and any person or persons who shall aid such person so applying to be treated in such dispensary, or who shall sign such certificate, knowing that such person so applying to be treated is not a poor person, shall be deemed guilty of a misdemeanor.

"Sec. 7. Power and authority is hereby conferred upon the societies known and designated as follows, namely: The New York County Medical Society, the New York Homeopathic County Medical Society, New York Eclectic County Medical Society, New York County Medical Association, the New York Medical Society for Advancing the Practice of Medicine, the Harlem Medical Society, the Eastern Medical Society, the German Medical Society of the City of New York, and the United Charities of the City of New York, under the certificate of appointment signed by its president and secretary and attested to by its corporate seal, to nominate and appoint one person who, with the persons to be selected by all of said societies, shall compose a board to be known as the 'Medical Board for the Supervision of Dispensaries Within the City of New York,' and such board shall have power to make such rules, regulations, and by-laws for its organization, government, and management; to adopt such rules and regulations with reference to the establishment, management, mode, and manner of carrying on and conducting such dispensary, and provide for the supervision thereof, and to adopt such rules and regulations with regard thereto as in the judgment of said board may be necessary for carrying out and giving force and effect to the provisions of this act, and upon the adoption thereof to cause the same to be distributed among such dispensaries, and all such dispensaries now in existence or hereafter to be established shall be subject to such rules, regulations, and by-laws, and subject to the supervision of the said board. Any vacancy in said board shall be filled by an appointment by the society to which the member belongs whose death, resignation, or inability to act created the vacancy.

"Sec. 8. Any person or persons or corporation so conducting or carrying on a dispensary, and violating any rules, regulations, and by-laws so made by said board after notice of the adoption thereof, and who shall fail to comply with any of such rules, regulations, and by-laws so adopted by said board, may be prosecuted by said board, or any officer thereof, and, upon conviction thereof, be deemed guilty of a misdemeanor, and shall be punished by a fine of not less than fifty dollars or more than two hundred and fifty dollars, or by imprisonment of not less than one month or more than six months, or both such fine and imprisonment for the first offense, and six months imprisonment for each subsequent offense.

"Sec. 9. The husband and wife shall be jointly and severally liable to pay for professional services of a physician rendered to them, or either of them, or any member of their family, and the joint or several property of the husband and wife shall be liable to levy and sale under an execution upon such judgment, except such property as may by law be exempt from levy and sale under an execution.

"Sec. 10. This act shall take effect immediately."

CORRESPONDENCE.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: May I call the attention of those of your readers who are thinking of coming to Philadelphia to attend the semi-centennial meeting of the American Medical Association to be held June 1, 2, 3, and 4, 1897, to the fact that there will be, in addition to the American Medical Association, at the same time a large mercantile convention, which will, to a certain extent, utilize a considerable number of the rooms in the various hotels. For this reason, it is advisable that physicians who intend to be present at the meeting should write at once to one of the following hotels engaging such rooms as they desire at the rates named:

HOTEL WALTON, Broad and Locust streets; $1.50 and upward per day, European plan; $4 and upward per day, Amercan plan.

THE COLONNADE, Fifteenth and Chestnut streets; $1 and upward per day, European plan; $3 and upward per day, American plan.

THE LAFAYETTE, Broad and Chestnut streets; $1 and upward per day, European plan; Table d'Hote: breakfast, 25 cents to $1; luncheon, 75 cents; dinner, $1.25.

THE BINGHAM HOUSE, Eleventh and Market streets; $2.50 and upward per day, strictly on the American plan.

HOTEL STENTON, Broad and Spruce streets; $2 and upward per day, European plan; $4 and upward per day, American plan.

THE CONTINENTAL, Ninth and Chestnut streets; $3 and upward per day, strictly on the American plan.

THE WINDSOR, Eleventh and Filbert streets; $1 and upward per day, European plan; $2 per day, American plan.

THE STRATFORD, Broad and Walnut streets; $1 and upward per day, European plan only.

GIRARD HOUSE, Ninth and Chestnut streets; $2.25 to $3 per day, strictly on the American plan.

HOTEL HANOVER, Twelfth and Arch streets; $2.50 per day, strictly on the American plan.

ALDINE HOTEL, Chestnut street, above Nineteenth; special rates to members of the American Medical Association, $2.50 per day on the American plan; $1 to $3 on the European plan.

The price quoted in each instance is for one person only. Rooms commanding only the lowest price are naturally limited in number. It is especially desirable that each member intending to be present at the meeting shall personally, or by letter, make his arrangement with the hotel at which he desires to stop. It is worthy of note that the rate of $1.50 per day at the Hotel Headquarters, the "Hotel Walton," is the rate for two people in one room.

All these hotels are within a few blocks of the meeting places, and most of them are within two blocks.

As a sub-committee of the general Committee of Arrangements has arranged clinical courses in all branches of medicine at the various teaching institutions and large hospitals during the week prior and following the week of the association meeting, it has been thought that a considerable number of physicians would be glad to embrace the opportunity of brushing up upon the various branches by attendance on these courses, for which no charge will be made by the gentlemen giving them, and as their stay in this city will therefore be more than a few days, it has occurred to the committee that some of the visiting physicians may wish to take rooms at some good boarding house. The Chairman of the Committee on Reception and Accommodation, Dr. G. E. de Schweinitz, 1401 Locust street, will be glad to send the addresses of such boarding houses to gentlemen desiring to stay here for a week or more.

The large number of gentlemen who have already signified their intention of attending the meeting, and the very large number of able and interesting papers already placed upon the section programs, indicate that this will be the most important meeting which the Association has ever had, and it is hoped that every physician who is a member of a regularly organized county medical society will make an effort to attend. The meeting halls for the various sections are situated so close to one another that different papers in different sections can be readily listened to during a single morning's session by those who do not wish to devote their time to one particular specialty.

Very truly yours,

H. A. HARE,
Chairman of the Committee of Arrangements,
American Medical Association.

PHILADELPHIA, March 24, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE ANNUAL COST OF ENTERIC FEVER—NEUROLOGICAL SOCIETY OF PHILADELPHIA—PATHOLOGICAL SOCIETY OF PHILADELPHIA—PHILADELPHIA COUNTY MEDICAL SOCIETY—ELECTIONS TO THE EPISCOPAL HOSPITAL STAFF.

PHILADELPHIA, March 27, 1897.

A FORCEFUL illustration both of the mortality from, and the monetary expenditure due to, enteric fever may be found in the statement made by Professor Mason of the Rensselaer Polytechnic Institute, in a recent lecture before the Franklin Institute, to the effect that the annual money loss in Philadelphia from typhoid fever is computed at more than one and one-quarter million dollars. In the five years, from 1890 to 1895, the average number of deaths annually from this disease was 523, and, rating each life as worth $2000, it will be seen that $1,046,000 of the estimated sum is accounted for, to which must be added the cost of 523 funerals at the low estimate of $25 apiece, making a total of $1,059,075 for those cases which end fatally. So much for the fatal cases; but Professor Mason does not forget that for each death from typhoid there are at least nine recoveries. Thus, 4707 recoveries, each ill for forty-three days (the average length of the disease as shown by an analysis of 500 cases in the Pennsylvania Hospital) take out of the taxpayers' pockets $202,401, reckoning each individual as earning one dollar a day. For physicians' fees and for nursing, at $25 for each case, for the total number of cases ill from the disease, $130,750 more is spent. The aggregate foots up the large total of $1,592,226; and, inasmuch as a system of water filtration, which would largely eliminate this waste of lives and money, is one of the questions of the hour in this city, the above statement appears to be especially timely. The consequences of a polluted water supply may not particularly impress our city legislators, when viewed from a standpoint of humanity, but can these figures of Professor Mason's, stated in cold dollars and cents, fail to impress the average practical politicians?

At a meeting of the Philadelphia Neurological Society, held on the 22d instant, Dr. Charles K. Mills showed two interesting cases of hereditary tremor. One case was that of a man in whom tremor of the head was present, apparently being produced by excitement, and allayed in a measure by recourse to alcoholic stimulation; the other case was one of tremor affecting the arms and head, in a girl of seven years. Dr. Mills, in his remarks on these cases, was inclined to look on them as diplegia, rather than tremor.

A case of isolated, bilateral paralysis of the abducens nerve, following an injury to the mastoid process was presented by Dr. A. G. Thomson. Dr. James Tyson, in the discussion following a paper by Dr. Joseph Leidy on neuralgia of the cranial nerves as a symptom of uremia, claimed that neuralgia of this type, being so common to other conditions, could not be considered at all conclusive, and added that the result of the urinary analysis would readily determine the condition.

Among the papers read at a meeting of the Philadelphia County Medical Society, held on the 24th instant, was a communication by Dr. H. A. Hare on the value of intravenous injections in the treatment of toxemia, giving the reports of two cases, one diabetic, the other uremic, in which he had employed this measure. The former case, a diabetic, of advanced years, with gangrene of the toe, during an acute toxemia received an intravenous injection of one quart of salt solution, and, after an improvement lasting twenty-four hours, died. The latter case, one of chronic parenchymatous nephritis, with widespread edema, and symptoms of uremia, improved after receiving two injections of one quart each, administered at intervals of ten days. Dr. Hare thought that the danger of air embolism from intravenous injections was overestimated, and stated that in neither of the cases quoted above were there any symptoms of a dangerous character, although air emboli were produced in both. An instance of remarkable deformity of the fingers from gout was also shown by Dr. Hare. The case was being treated by the hot-air method, with astonishing improvement, the nodules becoming a healthy red color—not the discoloration of an inflammatory process—softer, and partially absorbed, and there was much freer movement of the affected fingers. Two days after the beginning of the treatment, the patient had an acute, widely distributed attack of gout, which was perhaps due to the absorptive action of the high temperature, which at times reached 310 F., on the sodium urate deposits, in consequence of which they were melted down, and carried to other parts of the system. An interesting point in connection with this case was the fact that a skiagraph of the patient's hands showed that the Röntgen ray passed through the sodium urate deposits, evidences of these nodules being wanting in the print.

Dr. A. E. Roussel reported four cases of glandular fever occurring in the same family. His remarks pertained to the infectious nature of the unusual malady, to the differential diagnosis between it and scarlet fever, mumps, and the various forms of adenitis, and included a comprehensive review of the literature of the subject. Dr. J. C. Wilson, who opened the discussion on Dr. Roussel's paper, was inclined to urge caution in accepting a new nosological entity, and thought that some relation could perhaps be made out between glandular fever and scarlet fever.

At the last meeting of the Pathological Society, held on the 25th instant, Dr. A. E. Taylor reported the blood changes which occurred in an individual who had ingested several ounces of tri-nitro-benzol. Marked alteration in the staining properties of the neutrophilic granules was noted, these granules becoming oxyphilic, and staining readily with eosin, and with aurantia. There were no evidences of hemolysis, the erythrocytes staining normally, nor was there hemoglobinemia. When the patient recovered from the poison, twenty-four hours later, it was found that the granules of the polymorphonuclear leucocytes had resumed their accustomed reaction toward the neutral elements of the triple mixture.

Dr. H. L. Williams exhibited a dermoid cyst of the ovary, containing four teeth, a large roll of hair, and a a well-developed mammary gland with the nipple.

Dr. G. A. Muehleck reported a case of primary carcinoma of the thumb, and gave the statistics bearing on this infrequent lesion. Dr. Muehleck took the view that carcinomata of this locality, in contradistinction to sarcomata, gave a favorable outlook.

Kaiserling's method of preserving the color of pathological specimens was spoken of by Dr. J. P. Crozer Griffith, who detailed the technic of the process, and gave his experience with its use in a number of instances.

Other communications at this meeting were made by Dr. Joseph McFarland, who showed several phleboliths from the pelvic veins of a case of malignant disease of the pelvis, and by Dr. D. Riesman, who reported a case of amyloid degeneration of the suprarenal body, without pigmentation of the skin, or other symptoms of Addison's disease.

At a meeting of the Managers of the Episcopal Hospital, held on the twenth-fourth instant, Dr. Elliston J. Morris was elected Visiting Physician to the hospital; Dr. Clarence J. Garitee, Physician to the Medical Dispensary; and Dr. Charles H. Weber and Dr. Eugene Stadelman, Resident Physicians.

OUR PARIS LETTER.

[From our Special Correspondent.]

FRAENKEL'S TREATMENT OF LOCOMOTOR ATAXIA—MOTSCHUTKOWSKI'S SUSPENSION TREATMENT FOR TABES.

Paris, March 10, 1897.

Fraenkel, whose treatment of the incoordination of locomotor ataxia attracted considerable attention when he first began to practise it at Heiden in Switzerland, has been for nearly a year now demonstrating his method on patients at the Salpétrière in Paris. His success has been such as to warrant the belief that his method of treatment carefully, patiently, and properly applied, will do much to relieve the most distressing symptoms of tabes in the great majority of cases. When he first came to the Salpétrière some of the worst cases of ataxic incoordination in the service were put in his hands for treatment. Two of the patients had been bedridden for years, but all were distinctly improved after treatment. One of these, a woman who had not stirred from her bed for six years, now is able to go out into town alone with the help of a single cane. She can go up and down stairs, and can even walk with her eyes shut, yet the other symptoms of tabes remain (the absence of knee-jerks, the Argyll-Robertson

and there seems never to have been an hys-

bility, are devoid of proper sense of muscular fatigue, and may easily be encouraged to pursue exercises that cause exhaustion rather than education of muscles. The impaired nerve paths quickly resent the passage of unaccustomed impulses, and the intensity of attention required to carry out the exercises properly soon induces cerebral fatigue. For these reasons Dr. Fränkel insists that patients should not be asked to exercise for more than ten minutes at a time, with an interval of at least ten minutes, after which the motions may be repeated once more, usually not oftener. Twice a day such a *séance* of a half hour may be given. Exactitude in the accomplishment of the motions decided upon is the whole secret of the treatment.

When patients are bedridden, or when they are not easily able to stand up during the exercises, the purpose of the motions may be made more definite by putting around one leg a garter to which, in place of a buckle, is affixed a metal plate. The heel of the other foot is made to touch this plate, placed at different heighths on the leg, until the patient can accomplish the purpose readily even with eyes closed. Variety in the exercises is to be sought for, for they must be continued for weeks, sometimes for months, and Fränkel insists that the true end of the exercises must never be allowed to sink out of view. Not muscular exercise in the ordinary sense of the word, such as may be obtained from the repetition of any movement, is the end, but the reeducation of muscular attention by the careful repetition of movements with an exact and definite purpose.

Usually, patients themselves are very much encouraged from the outset. At the end of about two weeks there is a distinctly noticeable improvement in the coordination of movements which they have been practising, and this improvement continues for some time, until a certain stage of coordination, dependant on the extent of the disease, is reached. Whatever is gained remains as long as the disease itself remains stationary. Further progress of the disease will demand renewed education of the muscular sense, and at times their progress in coordination will render latent the advance of the sclerotic process in the cord.

For the more exact coordinate movements required of the hands, such as writing, for example, much finer and and more detailed exercises are required. It is surprising to see, however, how much improvement may be obtained in handwriting after a careful course of exercises in tracing various curved, spiral, and angular figures. In other relatively delicate movements for ataxics, such as grasping small objects, buttoning clothes, etc., the same improvement is noticeable after a course of exercises directed more especially to these ends, such as grasping at a given signal variously colored swinging balls, or picking out variously sized objects from a number scattered over the table.

As to the cases in which the treatment, when applicable, does not succeed (and they are rare), they are mainly those in which the intensity of attention required to direct the movements through the diseased nerve-fibers is too great for the patients to accomplish the effort demanded

---

standpoint the majority of the cases should treated by appropriate caustics in preference to removal by incision, and I take this opportunity o again stating my firm conviction of the correctnes of the view stated and defended at that time.

Although all authorities are agreed that ear treatment is proper and advisable in all cases c cancer, yet I can assure you that in an experience c many years, during which I have paid a great dea of attention to the subject, the majority of the case which have come under my observation have had a unquestioned existence of many months or years, th disease being heedlessly allowed to progress to suc an extent as often to have caused much deformity (deep and wide destruction of tissue, or even to th production of lymph-gland infection, although, as rule, the patients have been more or less under th observation of one or more physicians. On accou of this experience I have thought it proper, and po sibly of some advantage, to discuss the value and in portance of early treatment of cutaneous maligna epitheliomata, and to urge anew upon the professi

[1] Read at the meeting of the Northwestern Medical and Surgi Society, December 16, 1896.

of them. Dr. Fränkel points out that they are almost always people who have been characteristically awkward in their preataxic life, and whose general muscular sensibility is supposably congenitally impaired, capability for delicate movements being the nice adjustment between muscular sense and muscular motility.

In a certain number of cases the treatment is distinctly contraindicated. In acute tabes, where the pains are almost continuous, it would do harm rather than good, and when tried has always led to aggravation of symptoms. In patients suffering from arthropathies it is also contraindicated, or where for any reason there is suspected to be present that abnormal friability of the bones that causes so-called spontaneous fracture. Where severe vesical trouble exists, with a tendency to frequent recurrence of vesical crises, absolute tranquility is the only thing for the patient. Any amount of movement leads inevitably to aggravation of the extremely troublesome symptoms.

While putting the large number of tabetic patients that he has had through the movements Fränkel has found and described an additional symptom of tabes. It is the muscular relaxation that enables tabetic patients to put their joints in positions of hyperextension and hyperflexion that are impossible to normal persons. The hyperextension at the knee that gives tabetics the backward curve to their legs when extended has often been noted. A similar state of the muscles around the hip-joint and in the leg below it enables tabetics to place their legs at full length and without flexion of the knee in paralleiism with the trunk, or at least in a state of flexion, that is far beyond normal. Here in France, where symptoms are invariably connected with their discoverer's name, this condition of affairs is known as the Fränkel symptom, or muscular hypotonia. Its discoverer claims that it exists in the preataxic stage in a noticeable degree, and that it may be a valuable symptom of the incipiency of the disease.

The whole of Fränkel's work seems to bring out clearly the truth of what Marie stated so frankly in a lecture on tabes not long ago. Those who regard tabes as a disease, whose nosography is definite and determined, are reckoning without the suggestive developments that are constantly arising in connection with it. Fränkel's book, which I believe is soon to appear in German and French, will be welcomed by those who realize that it may shed new light on the practical side of the most interesting of nervous diseases.

Something about other therapeutic measures that are employed here in the treatment of nervous diseases may be of interest to the readers of the MEDICAL NEWS. Motschutkowski's suspension treatment for tabes is spoken of in terms of highest commendation on all sides. In certain cases it gives really marvelous results. The pains are rendered less severe and less frequently recurrent, the incoordination often becomes less noticeable, sexual potency returns, especially in young subjects, and the further progress of the disease seems to cease, at least for a time. At the Salpêtrière, by carefully limiting the length of the *séances* according to the patient's sensations, and only lengthening them very gradually by not allowing their too frequent repetition, and by avoiding entirely the application of the treatment in cases where there is serious heart disease, or considerable obesity, or where the patient experiences a painful sense of giddiness during or after the suspension, the serious results that have sometimes been reported from the treatment are never seen.

For the pains of locomotor ataxia a combination of phenacetin and antipyrin has been found more serviceable and productive of less annoying counter-symptoms than either of the drugs alone. Here no other drug is given or has been found of any use in tabes, though at Queen's Square Hospital for Nervous Diseases in London I found the use of chlorid of aluminium in 3-grain doses considered to sometimes lessen the troublesome symptoms of the disease and retard its progress. One is reminded of the oft-reported good derived from its chemical congener, the berated and overrated chlorid of gold and sodium in America.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting held Thursday Evening February 18, 1897.

The President, EDWARD G. JANEWAY, M.D., in the Chair.

A paper entitled

THE USE OF MODIFIED MILK IN HEALTH AND DISEASE

was read by THOMAS M. ROTCH, M.D., of Harvard University. (See page 417).

DISCUSSION.

ORIGINAL ARTICLES.

THE IMPORTANCE OF EARLY TREATMENT IN CUTANEOUS MALIGNANT EPITHELIOMATA.[1]

BY A. R. ROBINSON, M.D., L. R. C. P. AND S., EDIN.
OF NEW YORK;
PROFESSOR OF DERMATOLOGY IN THE NEW YORK POLYCLINIC;
ATTENDING PHYSICIAN TO THE NEW YORK
CANCER HOSPITAL.

THESE remarks will deal principally with the pathologic processes of cutaneous malignant epitheliomata; a consideration of the nature of the changes taking place in the tissues of the parts affected by the disease; how far our knowledge of these changes explains its clinical symptoms and course; what advantage is thereby gained in making a judicious choice and proper application of therapeutic measures; and, furthermore, what assistance a knowledge of all these things brings in support of the view that has been formed upon clinical observation that the earlier a cancer is properly treated for its removal the greater are the chances of cure.

Two or three years ago I read a paper upon the treatment of cutaneous cancers, and endeavored to prove that both from a theoretical and practical standpoint the majority of the cases should be treated by appropriate caustics in preference to removal by incision, and I take this opportunity of again stating my firm conviction of the correctness of the view stated and defended at that time.

Although all authorities are agreed that early treatment is proper and advisable in all cases of cancer, yet I can assure you that in an experience of many years, during which I have paid a great deal of attention to the subject, the majority of the cases which have come under my observation have had an unquestioned existence of many months or years, the disease being heedlessly allowed to progress to such an extent as often to have caused much deformity or deep and wide destruction of tissue, or even to the production of lymph-gland infection, although, as a rule, the patients have been more or less under the observation of one or more physicians. On account of this experience I have thought it proper, and possibly of some advantage, to discuss the value and importance of early treatment of cutaneous malignant epitheliomata, and to urge anew upon the profession the necessity and moral obligation of the prompt and proper treatment of this disease. I am satisfied that whether a cancer be situated upon the lips or cutaneous surface, proper treatment at an early stage usually enables the physician to give a favorable prognosis. Upon these grounds I now venture to discuss the subject, and trust the reading of this paper will be justified by the great importance of the subject.

A cutaneous or other cancer is at first a purely local disease, and not a local manifestation of a constitutional or general condition, therefore, a complete removal of the primary lesion before the disease has invaded other parts of the body is equivalent to a complete removal of the cancer from the body. Accepting this view as correct, our task is to consider the natural history of the disease, how it arises and progresses in its destructive course, and the factors or conditions which favor a rapid extension and hasten a fatal termination.

Cancers of the skin are usually described as occurring in three clinical forms: the superficial discoid, the papillary, and the deep or infiltrating. This division is of some advantage from a clinical standpoint, although it is not absolutely correct, as a primarily superficial cancer may have become deep before coming under the observation of a physician, or a primarily deep one may have become superficial, or either may have become papillomatous.

An epithelioma may commence as a scaly, eczematous-like lesion, or as a vesicle, papule, wart, tubercle, or nodule, and only close observation will enable the diagnosis to be made in some cases. The view that the seat of origin gives a type of form to the growth, the deep-seated nodular forms arising from the glands and follicles of the skin, and the superficial discoid ones from the epidermis proper, is not always correct, as many of the deep-seated, rapidly infiltrating epitheliomata arise from the rete. Furthermore, clinical observation does not enable the physician to state in a given case the structure from which the disease started. The clinical forms rather depend upon the seat of growth, the rapidity of the epithelial proliferation, the direction of its extension, the resisting power of the surrounding tissues, as well as the inflammatory or other changes occurring in the tissues of the affected part.

In all cases of malignant epitheliomata there are:

---

[1] Read at the meeting of the Northwestern Medical and Surgical Society, December 16, 1896.

1. An abnormal and excessive proliferation of epithelium.

2. The proliferation is an atypical one and is associated with the production of a poison which injures the surrounding tissues.

3. Changes, usually of an inflammatory character, occur in this surrounding connective tissue, lessening its resisting powers.

4. Invasion of the connective tissues by the new epithelial elements by way of the lymph-channels, and a tendency in the great majority of cases to secondary infection of lymphatic structures.

It seems that carcinomata contain a poison, a toxin—as shown by experimental injections and implantations of cancerous material—which injures connective tissues, differing in this respect from the benign epitheliomata. The more rapid the epithelial proliferation and the deeper seated the growth the sooner the connective tissue is likely to be invaded and lymph-gland infection to occur, since the amount of poison formed is in proportion to the rapidity of proliferation, and the injury to the connective tissue is in proportion to the amount of poison. As the *pars reticularis corii* offers considerable resistance to invasion as compared with the deeper and looser connective tissue, the deeper situated the cancerous growth the more rapid the invasion through the lymph channels.

Injury to the connective tissue of the part, from whatever cause, producing a more vulnerable condition of the tissue than that already caused by the epithelioma, favors a more rapid extension of the disease and should always be borne in mind when treating a case of this kind. The application, for instance, of a mild caustic, such as nitrate of silver, to an epithelioma, cannot destroy the growth except to a slight extent, even in the case of small and superficial cancers, but it acts injuriously upon the surrounding connective tissue, the nutrition of the part is lowered, and the vulnerability correspondingly increased, thus favoring epithelial invasion. How often have cases of epithelioma of the lip, skin, or cervix uteri assumed a rapidly progressive character in consequence of this meddlesome, injurious treatment? The method employed should always be effective and thorough; better no treatment whatever than one that is not only valueless for the object desired but hastens epithelial proliferation, invasion, and extension.

The epithelia of cancer can travel through lymph channels without causing any appreciable sign of inflammation in the part, or requiring a condition of inflammation to precede the invasion. This is shown particularly in connection with secondary invasion of the skin following mammary cancer. In some cases of slowly progressing superficial discoid epitheliomata the inflammatory changes may be scarcely observable to the unaided eye, and even on microscopical examination may present very slight signs of injury to the part—mostly signs of formative action, demonstrating that the resisting power of the connective-tissue has not been much impaired. If, however, the patient injures such an epithelioma by scratching, or in shaving, or by the use of a mild caustic, an erosion or ulcer forms, and the toxins from the pus organisms, intensifying the inflammatory process, increase the vulnerability of the corium and favor epithelial growth and invasion.

As this condition is liable to occur at any time, it follows that every epithelioma should be radically treated as early as possible after a diagnosis has been made. After ulceration has occurred and epithelial invasion is more advanced, the area to be destroyed in treatment for removal of the disease is greater and a reappearance of the disease more probable. In this connection it must be borne in mind that the pathologic epithelia are capable of independent locomotion and may travel some distance from the place of origin. In the deeper-seated forms the inflammatory changes are greater than in the superficial ones in consequence of the rapid proliferation of the epithelia and its consequent production of poison. As the resisting power of the deeper parts of the corium is less than that of the papillary portion the malignant processes always progress rapidly and soon invade the lymphatic glands; hence, such cases require early

treatment if a favorable result is to be obtained or to be expected.

Lymph-gland infection never occurs in rodent ulcer, and sometimes a superficial flat epithelioma may exist twenty years or longer without invading lymph glands, or even disappear without known surgical interference. When the epithelioma is situated upon the penis, lips, certain parts of the face, as just in front of the ear, infection is certain to occur, and takes place earlier than when the disease is seated upon the nose, ear, or eyelids. Of course an exception to this rule is occasionally observed.

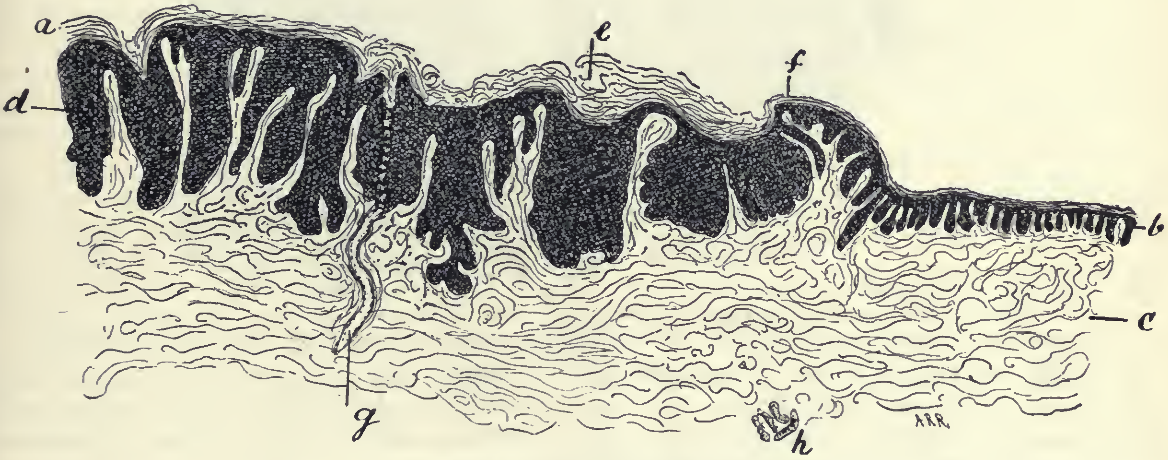
After these general considerations on the subject, let us consider the manner in which the disease extends at the seat of a primary lesion. In Fig. 1, from Waldeyer, is shown the manner of extension in cases of mammary carcinoma.

The drawing represents a terminal acinus and shows the epithelia arranged in an irregular, abnormal manner, and filling up the greater part of the lumen. The basement membrane of the acinus at its blind extremity has disappeared and the pathologic epithelia have invaded the periglandular tissue. The changes occur in the following manner: First, there is an abnormal proliferation of the glandular epithelium; then destruction of the basement membrane; and, finally, invasion of the surrounding tissue by way of the lymph channels. The drawing shows how the epithelia invade the tissues, as soon as the basement membrane is broken through, extending gradually in an irregular manner far into the periglandular tissue in the form of columns of epithelia or as single cells. Cancer elements had no doubt extended much beyond the limits of the section here represented. The most successful treatment for all cases of mammary cancer would clearly be amputation of the breast before the basement membrane has been penetrated, if a diagnosis could be made at that time. After that period the earlier the operation the greater the chances of being able to remove all of the disease.

The same method of extension, as above described, takes place in cutaneous cancer, where, with the exception of glands and follicles, there is no basement membrane to be penetrated. The majority of cutaneous epitheliomata start from the epidermis proper and not from the glandular structures. At first the growth is sharply limited, but sooner or later there is invasion of the corium and subcutaneous tissue. In Fig. 2 is shown, under a low power, a section of a very slowly spreading superficial epithelioma, which had already lasted several years, but still gave no signs of secondary lymph-gland infection.

The section shows the thickened epidermis and enlarged papillæ from downward growth of the rete. Note the slight change at the periphery as compared with the older part of the growth. The section includes a considerable piece of tissue—all beyond *f*—apparently normal to the naked eye. Microscopic examination showed atypical epithelial proliferation rather sharply limited at *f*, with epithelial invasion of the corium increasing in amount and depth toward the central part of the tumor. In these cases, as in cases of mammary cancer, there is first an atypical proliferation of the epithelium of the part, then invasion of the corium, slow at first, on account of the strong resisting power of the *pars reticularis corii*, and rapid when the deeper and looser connective tissue is reached. The same rule must hold true in these cases as in cases of mammary cancer, to wit: the earlier the growth is treated the more favorable the prognosis, and the less the deformity as a consequence of the necessary treatment.

Fig. 2.



Section of a Superficial Cutaneous Epithelioma.

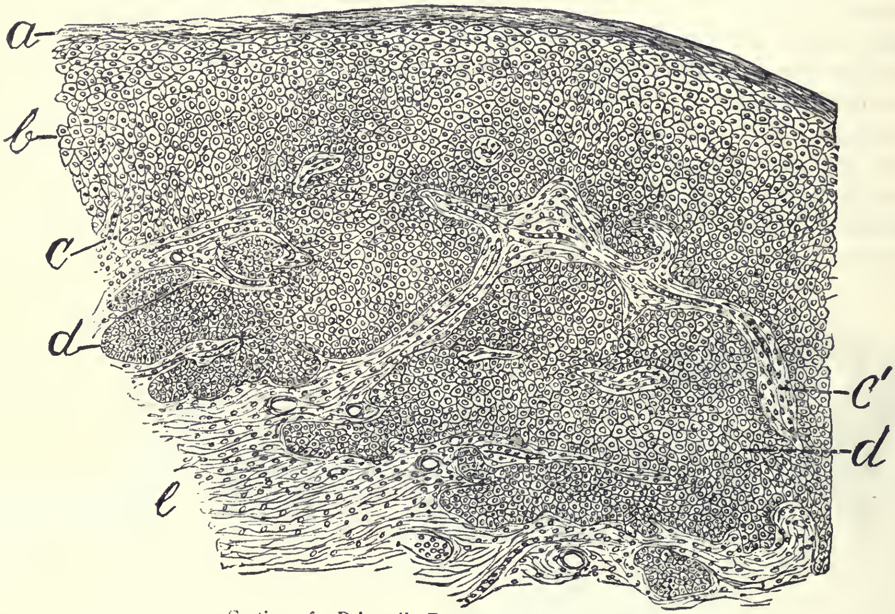
In the deep-seated nodular epitheliomata, the growth is much more rapid and the invasion of the corium occurs much earlier than in the form just described.

In these cases the surgeon should always act with promptness, lest secondary lymph-gland infection occur, and the case terminate fatally.

FIG. 3.



Section of a Primarily Deep-seated Epithelioma.
a, corneous layer; *b*, atypical rete; *c*, papillæ of corium; *d*, invading epithelial columns; *e*, corium with leucocyte infiltration.

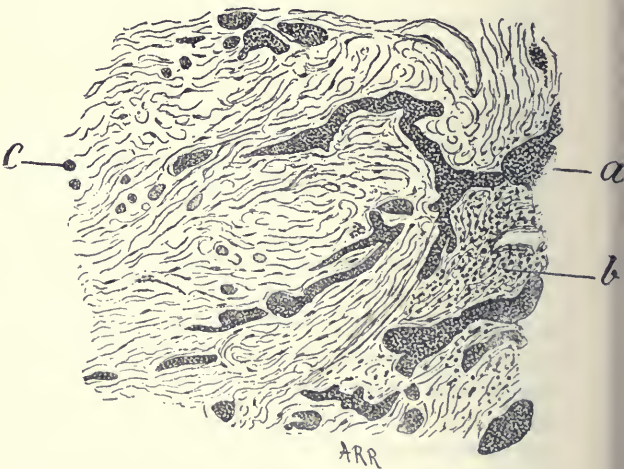
In rodent ulcer there is always atypical epithelial proliferation and invasion of the corium. The proliferation occurs slowly, and the individual cells seem to keep their filamentous connection with each other more than in the other forms of malignant epitheliomata. The invading cells usually form well-marked columns or cylinders, as shown in Fig. 4.

Having drawn your attention to the fact that in connection with the growth of the cancer, a poison is formed that causes inflammatory changes in the surrounding connective tissue; that the more the tissue is inflamed the easier it is invaded by the epithelia; that the greater and deeper the lymph-channel invasion the greater the danger of lymph-gland infection; it must appear clear to all that the earlier an epithelioma is treated the easier the task of removal, the less the necessary deformity from the operation, and the less the chances of a reappearance.

Let us, at the risk of some repetition, utilize the foregoing statements in a brief consideration of the clinical forms of epithelioma.

The superficial form can arise as a warty lesion, papule, erosion, or a scaly patch, and remain many years without attaining a greater size than that of a pea or bean. It shows a marked tendency to extension in a lateral direction, instead of in the depth, and, finally, may disappear spontaneously. I once saw a case in a man, now over eighty years of age, which I watched for fifteen years, the patient refusing treatment. During that period the ulcer spread over an area about two inches in diameter, never showing any signs of ulceration, although causing well-marked scar-tissue formation. Finally, it disappeared completely, after having traveled over a considerable part of the right cheek. I remember a case in a woman, about fifty years of age, in whom the disease had, within a few years, extended from one side of the forehead to the other, leaving a

FIG. 4.



Section of Peripheral Part of a Rodent Ulcer (Cylindrome).
a, columns of epithelia in lymph channels; *b*, small-celled infiltration; *c*, small column cut transversely.

cicatrix about three inches in length and one-third of an inch in diameter, and finally disappearing spontaneously. If all cases of superficial epithelioma ran such a favorable course, early treatment would not be necessary, but, unfortunately, such a course is a rare exception, and not the rule. I here show you a photograph of a case which, after lasting twenty years as a superficial epithelioma of the pearly variety, has commenced to extend into the deeper parts of the corium, and to encroach upon the eyes, and, if not promptly treated, will finally prove fatal. I also show you photographs of somewhat similar cases, and I have seen not a few where a fatal result followed on account of neglect on the part of the patient, or inefficient measures employed in the treatment.

I once saw a case which commenced as a papule on the lobe of the ear, and was treated by a physician with nitrate of silver, under the belief that it was not a cancer, but some non-malignant growth. The caustic, naturally, did not destroy the whole of the tumor, and within a few months there was secondary infection of the lymph glands of the side of the neck just below the ear, although the primary lesion had changed very slightly. Such a case is not often seen, yet the possibility of its occurrence should always be remembered by physicians. How easily such cases could be cured when seen at an early stage and properly treated.

In another case, a cancer that was not larger than a pea in size and macroscopically very sharply limited, started from the sheath of a hair follicle. Section of this showed great epithelial infiltration down to the subcutaneous tissue, and laterally much beyond its limit, according to the naked-eye appearance. I partly removed the lesion with a cutaneous punch, and then immediately applied a paste of arsenious acid, with satisfactory result.

In still another case the course of the disease was very rapid; the first lesion, commencing as a superficial eczematous-like patch, quickly assumed a malignant form, and proved fatal within a few months. The first lesion appeared upon the left cheek, and in a few months others formed upon the forehead, nose, and right cheek, with rapid destruction of the tissues and early infection of the lymphatic glands in front and below the right ear. An early diagnosis and prompt treatment would probably have cured this patient, but when I saw her operative measures, either by knife or caustic, were useless. I have seen other cases of this very malignant form, the *épithéliome foudroyant* or *épithéliome térébrant* of French writers, and they demand early and prompt treatment. I do not wish to be understood as saying that a cure cannot be obtained in quite a number of cases after the deep corium has been invaded, as I myself have frequently seen and cured such cases, but the earlier they are treated the more favorable is the prognosis. As the majority of all cases of cutaneous epitheliomata belong to the superficial form, proper treatment at an early stage robs the disease of much of its reputed gravity.

The superficial papillomatous form requires for its production a rapid proliferation of epithelium. It is seen principally upon mucous membranes and on the extremities. These tumors are not papillary in structure as is generally supposed, but assume the papillomatous form on account of the rapid epithelial proliferation. In connection with this rapid epithelial proliferation there is a large amount of poison formed, with consequent injury to the connective tissue, and when the barrier—the *pars reticularis corii*—is once broken there is rapid invasion of the corium, with early secondary lymph-gland infection. In an early stage, however, either as a primarily papillomatous growth, or as secondary to a superficial flat epithelioma their removal is not difficult, hence early treatment is strongly called for in this form of cancer. Even when situated upon the lips, if seen early, a suitable treatment by caustics gives most satisfactory results, both as regards cure and shape of lips afterward.

The deep-seated or nodular epitheliomata may occur as a primary growth or from extension downward of a superficial one. Some of these deep-seated nodular epitheliomata, especially when situated upon the scalp, are difficult to diagnose at an early stage, as they resemble somewhat fibroid or sebaceous tumors, and thus valuable time is sometimes lost, as an incomplete operation is performed in the belief that the growth is not a malignant epithelioma. I recall a case operated upon, ten years ago, by an excellent surgeon, thinking it was a so-called sebaceous cyst of the scalp. The growth was upon the vertex. It reappeared a few months later, and when I saw the woman some time afterward the growth was about one and a half inches in diameter and presented the character of an ulcerating epithelioma. The diagnosis of epithelioma had already been made by the physician from sections of the tumor removed by the surgeon. No gland infection could be recognized, and so I removed the growth by a caustic paste. From that time until her death—four years—there never were any signs of a reappearance at the seat of the primary growth, but within six months of my operation a tumor appeared upon the side of the head, followed soon afterward by another behind the ear, and infection of the lymph glands of the side of the neck. Another case, in a little girl only twelve years of age, in whom the growth was in the same location, was operated upon last year for a supposed sebaceous tumor-cyst, and the final result will be a similar one, as the glands of both sides of the neck are now enormously swollen.

The clinical character of these cases of the scalp should be sufficient for accurate diagnosis. The growth first appears as a small nodule, deeply seated, sharply limited, and somewhat movable. It gradually increases in size, feels hard, firm, or elastic; the skin over it appears at first perfectly healthy and non-adherent to the growth; later, it becomes adherent and pinkish or reddish in color, and traversed by dilated vessels. The base is deep-seated, and evidently extends near to the periosteum. Operations for their removal should be early and very complete, destroying part of the periosteum if necessary. In a doubtful case a microscopic examination should be made at the time of operation, so that if pronounced cancer the operation be regulated accordingly.

Pigmented epitheliomata are rare; they pursue a very rapid and fatal course, owing to the active proliferation of the epithelia and power of locomotion, therefore require very early treatment. As they arise from moles or nævi, any signs of nutrition changes in these structures in advanced life, changes causing them to become firmer or to bleed easily, should be indications for the removal of the latter.

Rodent ulcer is a variety of epithelioma in which secondary lymph-gland infection does not occur, but the disease, if untreated, pursues a slow but destructive course, and invariably leads to death from local injury to the region invaded. If treated early a favorable prognosis can sometimes be expected, but in a later stage I think these cases are hopeless. We are not yet in accord as to what justifies the diagnosis of rodent ulcer, and the subject requires new studies. Personally, I do not believe it depends upon the same agent or conditions that exist in the other forms of malignant epithelioma, and that the epithelial proliferation is a secondary process. I have so far always found changes in the peripheral nerves, but whether they are primary or secondary I am not able to state. The fact that the system has sufficient physiologic resistance to prevent lymph-gland infection would show the cause of the epithelial proliferation to be different in the two kinds of epithelioma. As regards the epithelia present, there is no distinct type, either as regards size, staining qualities, or arrangement.

Paget's disease of the nipple should be diagnosed early, and the breast amputated without delay. The diagnosis, however, should be positive and correct, as no woman should undergo unnecessarily an operation of this kind. I have known consulting physicians advise such an operation too hastily. A proper microscopic examination should enable one to confirm or reject the diagnosis of Paget's disease.

In conclusion, permit me to say that I am certain a clear knowledge of the pathologic processes in cancer is essential to the successful treatment of the disease.

THE MEDICO-LEGAL ASPECT OF INSANITY, WITH REFERENCE TO COMMITMENTS, JURY TRIALS, AND EXPERT TESTIMONY.[1]

BY JOSEPH J. O'CONNELL, M.D.,
OF BROOKLYN;
EXAMINER IN LUNACY FOR THE DEPARTMENT OF CHARITIES AND CORRECTION, KINGS COUNTY, NEW YORK.

WHEN we undertake the study of insanity we find that the definition of the term conveys a widely different meaning to the community, to lawyers, and to physicians. I have often had the question, "What is Insanity?" asked me in court, and have heard it many times propounded to my professional associates. I have answered it to my own satisfaction, and heard it answered with every confidence by others, but each and every time I have heard the definition picked apart in the cross-examination by a cunning lawyer, until only a very slight network remained to sustain it. In referring to the works of medical writers on the subject, I have found nine in which no attempt at a definition is made, while three of the authorities are of the one mind; *e.g.*, that it is impossible to give a definition that will bear legal analysis, although each defines it for practical purposes. Allan McLane Hamilton states that "it is a favorite method with lawyers to make the medical witness commit himself in defining the word, and then hopelessly entangle him in quibbles."

The more I consider the subject the further am I from the opinion that it is possible to frame an answer that would be acceptable to all; that is, what insanity is, when it begins, or where it ends, aside from those cases with a sudden onset, or such that end in death. There is no standard for sanity or insanity. One extremist said that the world was composed of freaks and one sane person; and when asked whom he considered the sane person, answered, "Myself." Boileau said, "All men are insane, but some are able to hide it better than others." Montesquieu said, "Insane asylums were built in order that the outside world would consider itself sane." Haslam, one of the first alienists in England during his time

---

[1] Read before the Kings County Medical Association, December 8, 1896.

I am indebted to the writings of Drs. Charles F. Folsom, Allan McLane Hamilton, John C. Shaw, John Sibbald, and Theo. Kirchhoff, and to Redfield's "Law and Practice of Surrogates Courts," for many of the laws, quotations, etc., in this article.

(1832), testified in court that he had never seen a sane man in his whole life, adding, "I presume the Deity is of sound mind, and he alone."

We have, then, to consider insanity according to the different accepted ideas. The community usually considers an insane person to be one with a wild and excited manner, constantly considering the destruction of some person or thing, an individual that must be placed under restraint or closely guarded to keep him from fulfilling his criminal desires; or else they believe the condition to involve the opposite extreme, as expressed in marked dementia with incoherent speech, confused ideas, uncleanly habits, and poor physical condition. This is the popular idea of the class of individuals that should be committed to an asylum for the insane. Then, again, other persons who have overwhelming delusions, strange though mild actions, irritable dispositions, peculiar dress, and such like, are looked upon as cranks, freaks and hobbists, but if asked if they consider a person of this type of sound mind, they answer in the affirmative, and state that his manner is only peculiar and erratic. I have often found that the closer the relation, or the better the acquaintance, the slower are the changed condition of relative or friend observed. This is the chief reason why we have been troubled so much of late by the so-called harmless cranks, who have been doing so much damage to the community by removing so many useful persons from the world. It has often been said that if it was left to the average man to decide as to the mental condition of the inmates of an asylum, he would consider seventy to eighty per cent. of them sane, so well can they hide their delusions.

Lawyers take a much narrower view of insanity than physicians; they consider insanity only so far as it affects the safety of person or the preservation of property. A lawyer considers whether a person is competent to perform certain acts which he may be called upon to perform, or responsible for certain acts which he has committed. Sir James Stephen said, in speaking of insanity: "It means conduct of a certain character—a physician would mean certain disease." Sir Edward Coke said, "A man is insane only when he is *non compos mentis*, or has wholly lost his memory and understanding." A man is not insane, in the sight of the law, unless his act is traceable to, or its nature has been determined by, mental disease affecting his free agency; in other words, unless insanity caused his act either wholly or in great part.

Section 21 of the Penal Code, in reference to irresponsibility, etc., of idiots and lunatics, reads as follows: "A person is not excused from criminal liability as an idiot, imbecile, lunatic, or insane person, except upon proof that, at the time of committing the alleged criminal act, he was laboring under such a defect of reason, as either, first, not to know the nature and quality of the act he was doing; or, second, not to know that the act was wrong." This section has been criticised because it excludes consideration of the question whether the accused possessed sufficient power of self-restraint to forbear the commission of an act which he clearly perceived to be criminal. A desire for self-destruction, and the adoption of means to secure it, do not of themselves indicate a mental impairment which has advanced to the stage of irresponsibility, otherwise the law would not declare the attempt to kill oneself a crime.

In relation to will-making, Redfield states: "The doctrine that any insane delusion incapacitates from making a will has commanded the assent of some high authorities, but the weight of authority and the better opinion accord with the rule settled in this State, by which mental capacity is measured, as in every other legal aspect, by its relation to the act. Hence, a person having any insane delusion relating either to the property, to the persons concerned, or to the provisions of the will, is incapable; while delusions which in no way relate to these do not, as a matter of law, incapacitate, for they involve no more likelihood of actual incapacity than many other latent causes. A person may have an insane belief or delusion as to one or more subjects, and not as to others. The question, in respect to the testamentary capacity, in the abstract, is: "Had the testator, at the time, a sufficiently sound mind to make a will?" but, practically, in most cases the question is: "Had the testator a sufficiently sound mind to make the will in question?" There is but one standard of testamentary capacity known to the law of this State, and that is embraced in the inquiry, "Was the decedent *compos mentis* or *non compos mentis*, as those terms are settled in the law, at the time of the execution of the instrument?" A man's ability to transact his ordinary business with judgment and discretion is very strong, if not conclusive, evidence of testamentary capacity. A monomaniac may make a perfectly valid will, if the delusion which affects the general soundness of his mind has no relation to the subject or object of the will.

Physicians consider insanity from a less limited point of view than lawyers. A medical man applies his mind to its study, so as to ascertain how far he may infer from the evidences of mental action the existence of morbid conditions, with a hope to alleviate or remove them. The cases in which a physician is called upon to define insanity, as the term is used by lawyers, are:

(1) To secure limitation or control of an individ-

ual's actions, usually by guardianship. (2) To control him absolutely in an asylum. (3) To estimate his culpability or criminality, or his capacity to make a will or contract, or to transact business. The definitions for insanity, as given by medical writers on the subject, are somewhat similar. Bucknill says: "It is a disease of the brain (idiopathic or sympathetic) affecting the integrity of the mind, whether marked by intellectual or emotional disorder," and he also recommends the medical witness to add the words, "that the cerebro-mental disorder is such as to suspend or impair the action of the healthy will." Maudsley's definition is as follows: "Insanity is, in fact, disorder of brain, producing disorder of mind; or, to define its nature in greater detail, it is a disorder of the supreme nerve centers of the brain—the special organs of mind,—producing derangement of thought, feeling, and action, together or separately, of such degree or kind as to incapacitate the individual for the relations of life." Dr. Folsom states that any definition of insanity would be incomplete without the statement of Hughlings Jackson's view, that is, that "disease only produces negative mental symptoms answering to dissolution, and all elaborate positive mental symptoms (illusions, hallucinations, delusions, and extravagant conduct) are the outcome of activity of nervous elements untouched by any pathological process. The insane man's illusions, etc., are not caused by disease, but are the outcome of activity of what is left of him (of what the disease has spared), of all there then is of him. His illusions, etc., are his mind."

The simplest division of insanity for all practical purposes is as follows:

Idiocy,
Imbecility,
Mania, } Acute and chronic,
Melancholia, } Acute and chronic,
Dementia (primary and secondary),
General paralysis of the insane.

These have many subdivisions, which are named and classified differently by almost every writer on the subject. Many varieties derive their names from the causation or circumstances with which they appear; they are symptomatic conditions, and are connected with emotional excitement rather than intellectual disturbance. The division I have before described is usually accepted in a court of law without further questioning, and it is better for the medical witness to adopt it than to confuse the court and jury by the subdivisions. This is especially advisable, as a lawyer will often ask a medical witness if he considers such and such a person an authority on the question, and if he answers affirmatively he will be informed that his classification is much different from the one just stated.

Some writers claim that it is impossible to make a distinction between idiocy and imbecility; others differentiate them as follows: "Idiocy is a non-development of the brain; imbecility is an arrest of the development of the brain that takes place after birth, usually due to some of the diseases of childhood, that is, it is a permanent arrest, as the brain is unsusceptible to training, except to a very limited degree." Idiots have been trained so as to assist themselves in many ways; under the guardianship of our institutions many have been taught minor trades. This, of course, is not the case with all, as in a large proportion of cases it is impossible to teach them even the alphabet. The idiot's brain therefore remains in the same condition as that of the new-born child, and no development takes place except in a few cases and under the most persistent training.

The Legal Status of the Idiot.—Though in the United States the idiot is deprived of all his other rights, he is, curiously enough, permitted to vote. He is considered incompetent in the matter of will-making, and obligations of any kind contracted by him are null and void, because of his want of comprehension of the nature of these acts. He is also considered irresponsible criminally when it can be shown that the crime is motiveless and unintentional (in their legal sense), and the existence of the will is disproved. In these cases there is neither realization of punishment or consequences.[1]

The description and definition of other forms of insanity, known under the classification as manias and melancholia, is given in the simplest manner, I believe, by Griesinger, as follows: (1) "The diseases with mental depression are: hypochondriasis, simple melancholia, melancholia with stupor, melancholia with destructive tendencies, and melancholia with persistent excitement of the will or impulse (moral insanity). (2) Those of mental exaltation—mania and monomania. (3) Those of mental weakness—chronic mania, dementia, idiocy, and cretinism."

Probably the most prominent mental disease about which a physician is called into court to testify, as to some person's testamentary capacity, is general paralysis of the insane, which is also known as paresis, paralytic dementia, paretic dementia, progressive paralysis of the insane, softening of the brain, and sclerosis of the brain. In the earliest stages of this disease, when the manner and habits of the patient are changed and he becomes careless and indifferent regarding his personal appearance; when his ideas become expensive and he makes contracts for property or goods that he is unable to pay for, and buys goods that he has no use for, it is then that the medical witness is called to defend him in a court of law for his irresponsible actions. In this same disease a remission takes place in which the patient acts and talks in a rational matter, and it is during this remission that it has been questioned if such a person is capable of making a valid will or contract. I cannot see how a person can have complete reasoning power, even sufficient to consider properly a business contract or compose a will, if his brain has undergone that morbid change that we know takes place in paresis, knowing, as we do, that during the remission or any part of the disease no repair takes place. The length of time of these remissions varies. Baillarger has reported nineteen cases in which the period of remission varied from one month to two years. Dagonet believes that during the remission there is a state of mental feebleness which is incompatible with perfect responsibility.

---

[1] Hamilton, "Medical Jurisprudence," p. 126.

In the matter of the commitment of the insane past legislation has made certain radical changes from former statutes. Under the new law, which is known as the "Insanity Law," no person can be committed to an institution for the care and treatment of the insane except upon the order of a judge of a court of record, such order being granted upon a verified petition and a certificate of lunacy signed by two medical examiners, after notice to the alleged insane person or some other person to be designated by the court, unless the court sees good reason to dispense with such notice. A hearing may be had of the judge to whom the application is made, at his discretion, or upon demand of the alleged insane person. A very important requirement of the new law is that no insane person shall be confined in any prison, jail, or lock-up, unless he or she is dangerous and there is no other suitable place for confinement. This does not refer to a person under charge of committing a crime. The examiners must not be connected in any way with the prison, penitentiary, reformatory, or such penal institution where the alleged insane criminal is confined. This new insanity law has many advantages and some disadvantages. The service of a notice upon the patient at least one day before the application is presented to the court, stating that an application is to be made for his commitment to an asylum, is apt to do harm to the patient. It will have a tendency to excite those suffering from mania, and to still further depress melancholiacs. The law allows the court to dispense with such notice, but why should it be served on one and not on all, if it is any protection? I do not know of one patient in my experience as an examiner to whom it would not be more injurious than beneficial. Another section of the law I believe gives a police official too much latitude: "Any person apparently insane, and conducting himself in a manner which in a sane person would be considered disorderly, may be arrested by any peace officer and confined in some safe and comfortable place until the question of his sanity be determined as prescribed by the chapter." It is my impression that this gives a sort of autocratic power to the police, and will cause much unpleasantness.

The rules laid down for the examination of an alleged insane person are as follows: Get a history of the patient's family from a relative or friend if possible, also a description of the actions and manner of the patient from childhood until the present change occurred, so that an idea may be gained as to his normal condition; also, a history of the present attack, with the predisposing and exciting causes. With such information visit your patient with a manner that will gain his confidence from the beginning. Do not give him any impression as to the object of your visit. Converse with him on some subject other than that of his delusions, and while so doing observe carefully his physical condition, his actions, and his personal cleanliness. After you have thus got the confidence of your patient, gradually broach the subject of his delusions, noting carefully the interest he takes in them. It is often necessary to differ with the patient after you have conversed with him on his delusions in order that you may test his disposition. The commitment paper should contain a full account of his irrational ideas and actions so that the court may readily see why the patient is considered of unsound mind and a subject for an asylum. It is possible that the examiner may be called into court at a later date, and a certificate with a good description of the case will refresh the memory very much.

The same method of examination is usually followed in the alleged insanity of criminals, although the examiner begins his examination with a biased mind. There is an object here for feigning insanity, and it is so often practised by persons of this class that it requires more positive evidence to satisfy the examiner than is the case with the ordinary insane. The most difficult examination to make, especially in the case of a criminal, is when conversation must be carried on through the aid of an interpreter, as it is often by the manner in which a question is put and the way it is answered that an idea is gained of a person's delusions and hallucinations. In view of the thorough examination of an alleged insane person, the amount of knowledge and training that is required for such an examination on the part of the medical examiner, and the reviewing of the testimony by the court, it seems strange that when an application is made for the appointment of a committee of person and estate, or when a habeas corpus proceeding for the discharge of such person is instituted, that the court usually directs that such hearings be held before a jury. It is my impression that a jury of laymen is incompetent to judge as to a person's sanity, and I have often thought that such trials should be held before a judge, or before a commission composed of one lawyer and two physicians.

The Medical Witness—Expert Testimony.—The absurd verdicts that have been rendered in so many cases are not alone chargeable to the jury, but are often due to the laws of our State that allow too much latitude to lawyers in the examination of the medical witness. During the cross-examination an effort is made to entangle the witness by some catch question, or to make him contradict himself in some way so that he will appear in a ridiculous light before the jury. Such an examination may have some influence upon a jury, but I believe it is of minor effect as compared with the testimony of a class of men who have testified in our courts frequently of late years under the guise of experts. That these men should appear on the witness stand and have their testimony weighed in the same manner as that of the honest, conscientious, and intelligent members of our profession, seems to me to be an outrage. It is for the medical profession to put a stop to this abuse. So-called expert testimony to-day has been reduced to such a level that many of the reputed experts are only to be classified as criminal rogues. I believe, as a remedy for this evil, that all experts should be selected by the judge presiding at the trial where such testimony is required. At the request of counsel for either side the court shall appoint one or more experts, but not more than three, and their expenses shall be charged as court costs. I would suggest that in every district of the Supreme Court the Governor of the State appoint a commission of five medical men, with power to select such physicians as experts as are considered authorities in their respective branches of medicine, and that its selection should receive the unanimous approval of the judges of the Appellate Court of the same division. This would separate the direct witness in a case from the medical expert, and we would then listen to expert testimony with an eager ear, knowing that the witness was an authority on the subject at issue, was testifying to the truth, and was bringing to bear the information of a trained mind.

DISCUSSION.

Hon. Willard Bartlett, Judge of the Supreme Court, Kings County: Let me speak first of what Dr. O'Connell has said in regard to medical expert witnesses. To a lawyer, a chemist, who is called upon to give evidence in a murder trial as an expert, is not what would ordinarily be termed an expert witness, unless he is called upon to state not merely facts observed by him as a chemist or physician, but to testify to matters of opinion; and it is to this class of witnesses rather than those who simply detail facts that lawyers generally refer as expert witnesses. The proposal is made here, and I have heard it made many times before, and have discussed it myself in a paper I read some years ago before the Society of Medical Jurisprudence in New York, that there should be appointed by the court, or in some official manner, an expert to give testimony in important cases, so that, for example, when a question as to insanity comes up before a judge and jury, after all the testimony as to matters of fact has been given on one side and the other, this expert may be called upon to give his opinion in answer to a hypothetical question, or otherwise, as the court deems best adapted to illustrate the truth. As to this, I wish to make one suggestion to the medical profession. A patient who has been treated by his physician for months and years is alleged to be insane, and the question of his insanity is being tried. The physician is prepared to show, so far as his testimony goes, that the man is perfectly sane. He can go amongst the medical profession and find a score of physicians of the highest character who are all ready to endorse his opinion, and to take the stand and give evidence to that effect. He goes into court and testifies, and the other gentlemen take the stand and testify, all being equally unknown to the judge and jury; and perhaps, after giving this testimony, somebody appointed by some authority, political or judicial, some physician, whose ability may be questionable, takes the stand and gives evidence with all the weight of his official position in a contrary direction. Would that be fair or desirable? Is the suggestion that is so often made that we should have a class of official witnesses a solution of the problem? The problem is a serious one and is not easy of solution, and I am afraid that this would be very far from a satisfactory solution. One point more. The idea of official witnesses is totally opposed to all prevailing ideas of American and English jurisprudence. It would be a departure in a direction contrary to the spirit that has given rise to our free institutions. It may be an improvement, but it is radically different; and we should consider that before we determine as to what is a true solution of this problem. That is all I wish to say on the subject of expert testimony.

What I have to say as to the rest will be devoted to the relations of the law to insanity. Dr. Bierwirth, in inviting me to come here this evening, said he particularly wanted to have my views on this subject and upon the recent legislation which went into effect in July last in regard to the commitment of the insane. Now, our law dealing with the insane substantially treats the subject in four aspects: (1) Mental derangement, so far as it justifies the restraint of personal liberty. (2) Mental derangement, so far as it relates to the property of the patient and taking away from him the control of that property. (3) Insanity, as affecting the capacity of the patient to execute wills and contracts generally. (4) Mental derangement, as an excuse for acts which would otherwise be criminal.

As to mental derangement, which justifies the restraint of the individual, or the commitment of the insane, I think there would be a better understanding between doctors and lawyers if the precise objects of the law were understood. If a man is taken ill in his own house with any sort of malady, the law does not ordinarily undertake to interfere with the physician in his treatment of that patient. He does substantially what he likes. And if the man is harmlessly insane in his own home, the law does not undertake to say what should be done or not done, except to see that the physician treating him shall possess and exercise ordinary skill in his profession. The chief reason why the law interferes at all in regard to lunatics is because of the acknowledged necessity that some sort of physical restraint must often be exercised; and all that the law has attempted to do is to see to it that in those cases where physicians find it necessary and proper to exercise this physical restraint upon the liberty of the citizen, such restraint shall be exercised only under circumstances clearly justifiable. When the law does that, it does enough; when it does more than that, it does too much.

Under the old system the process of placing the insane patient under restraint was very simple. An examination had to be made of the patient by two physicians who had practised medicine for three years and were of good character, their qualifications in this respect being certified to by some judge of a court of record. Without any prior judicial approval whatever the patient could be sent to an insane asylum for a few days until judicial sanction was secured. Under this law I have had much personal experience. There were few evils, and certainly no necessary evils, provided the physicians did their part of the work in the right manner and the judges did their part; and if the physicians were properly qualified and had made the examination with the necessary care, and the judges had examined the cases, and had seen at least one of the physicians who had signed the certificate, the system worked very well. Of course, there were evils if either the physicians or the judges were lax. For example, it is a mere mockery for a man who is not a physician to come into a court with fifty certificates of lunacy, and expect the judge to sign his name to every one of them without any inquiry whatever. I repeat, such procedure is a mere mockery, and affords no protection whatever to the persons whose liberty is about to be restrained; but a proper degree of care would prevent any such evils as this.

The law now is changed very much. Dr. O'Connell has referred to some particulars in which it has been changed. There can be no exercise of such restraint without a prior judicial order or adjudication that the patient is insane. It is objectionable, it seems to me, to require such a positive judgment to this effect in all cases, as a condition precedent to the temporary confinement of the insane. There are many cases in which the mental derangement is not permanent and in which the patient, if he or his relatives could have anything to say about it, would prefer that there should not be on record in the courts so formal a finding of insanity as is now required. Under the old system a certificate from two physicians, that they deemed him insane, was necessary, but there was no formal adjudication of insanity. This is absolutely indispensable now. There is another class of cases where it is important to proceed with rapidity. These may be defined as emergency cases, in which it is better for the patient himself and for his family that he be placed under restraint; and the expediency of restoring the old law to the extent of providing for at least temporary restraint in such cases, without adjudication, seems to me quite manifest.

I will pass on as rapidly as possible to two or three other points which I have in mind. It must be remembered that all these proceedings with respect to the commitment of the insane upon such certificates and upon such judicial orders as I have alluded to, have no direct effect whatever upon the patient's civil rights, or his right to vote or control his property. The only effect of all these proceedings is to justify his restraint. If you wish to take even one dollar from him for his own benefit the proceedings must be entirely different. Our jurisprudence on this subject is derived from England, and as in England, the assistance of a jury is necessary. A third aspect of insanity with which the law deals is that relating to the capacity of the patient to make wills and contracts; and as my friend, the Surrogate, is present, and is, I understand, to favor us with a few remarks, I will not dwell any longer on this phase of the subject.

As to insanity and mental derangement as an excuse for what would otherwise be regarded as criminal acts, perhaps there has been no subject on which the medical and legal professions are more hopelessly divided than upon this. The law has been criticised again and again for the inadequate and unsatisfactory character of the legal rules as to what degree of mental derangement shall be deemed sufficient to constitute an excuse for crime. About this I only wish to make one observation. The difficulties are far more exaggerated in discussion than they really are in practice. I have rarely seen any criminal case in which, after the conclusion was finally arrived at by judge and jury, the results would not meet the approval of a body of medical men like the Kings County Medical Association, if carefully reviewed. We do better than you suppose would be possible from the law as you understand it. Theoretically it is not perfect; but in practice it works, on the whole, very well, when the difficulties in the way of devising a better system or a better definition are considered.

I should be very glad to cooperate with any movement coming from the medical profession toward making the law theoretically more perfect; but taking into consideration all the difficulties of the matter I think we have every reason to be satisfied with the results as they are achieved in the courts to-day.

HON. GEO. B. ABBOTT, Surrogate of Kings County: The objections usually urged against a will offered for probate are three: First, that it has not been executed in accordance with the requirements of the statute; second, that the testator did not possess testamentary capacity at the time of execution; third, that the will was procured by fraud and under influence. Of these, the second objection, that of testamentary incapacity, is the one most often litigated, and many times very perplexing and difficult problems arise, as I have found in my experience as surrogate. The question for the court to decide in regard to testamentary capacity is, "Did the testator comprehend the nature and extent of his property, and who have just or natural claims upon his bounty in its disposition?" Many people are superstitious in regard to making their wills. Instead of making them in the prime of life, or when at their best mentally and physically, they put it off for one reason or another until at the point of death. The questions the court have to consider are: "Under what circumstances was the will executed? Did the testator possess sufficient testamentary capacity to know what he was doing?" and, "Was it executed of his own free will?"

Some lawyers have peculiar ideas about testamentary capacity. A lawyer some time ago came into my court, alleging that a certain will had been made while the testator was insane. I saw nothing in the case indicating mental trouble on the part of the testator; but the lawyer declared that there was no doubt as to his absolute insanity. His first witness was a barber, who stated that the testator went to his shop to be shaved, and as soon as he sat down in the chair he went to sleep, and therefore he was insane and incapacitated for making a will. Under these circumstances, I am afraid I should not be competent to make a will myself, as I usually go to sleep in my barber's chair.

The Hamilton will case was tried before me. It was one of the most difficult and perplexing cases that I have ever had to deal with; one of the "border-line" cases so difficult to dispose of satisfactorily. In relation to expert testimony, it affords ample illustration of how unsatisfactory this class of testimony often is. The testator executed his will on the twenty-seventh day of October. It was drawn up by a lawyer, who also witnessed the will. The other witness was of good reputation, but not a professional man. The testator's family physician had seen him on this same day. About ten days later he had an acute seizure, and became violently insane. Then experts were called in who saw him under these conditions, but who had not seen him previous to that time. The testimony of the lawyer who drew up the will and subscribed to it as a witness, and that of the family physician, was so clear and explicit as to the capacity of the man on the day on which the will was executed, that I made up my mind to admit the will to probate. The expert witnesses were numerous, Dr. O'Connell, whose paper you have just heard read, being one of them. A hypothetical question, difficult, intricate, and of great length, was propounded, and the medical men called by the contestants answered it with great unanimity, agreeing that the testator was of unsound mind. The experts called in by the other side were required to answer a hypothetical question of almost a similar nature, and they were quite sure that the testator was perfectly sane. Under these circumstances, you can see how unsatisfactory such testimony is. I concluded to be guided by the testimony of the lawyer who drew the will and the family physician, and admitted it to probate. A jury subsequently reached a different conclusion. We have many cases of this kind in the courts, and you can readily see that when the opinions of eminent experts, on the same statement of facts, are so conflicting, their testimony is not of much service to the court in reaching a decision.

It may be possible to formulate some system which will make the introduction of expert evidence more satisfactory to medical men and the courts; but, as Judge Bartlett has just remarked, it is a question which is very difficult of solution, and after much consultation with other judicial officers on the subject, I am not sure but our present system is the only practicable one, after all.

DR. J. C. SHAW: As Judge Bartlett has placed the matter so clearly before the meeting there is little for me to say. The most objectionable feature in the law of commitment is the service of the paper on the patient twenty-four hours before committing him to an asylum. Two or three weeks ago I was compelled to appear before the judge of one of our courts in the case of a man who was suffering from paresis in the early stage and request that he permit the service to be made on the man's wife. It certainly would make such a patient worse to present this paper to him stating that he was to be adjudged a lunatic.

Lawyers have been in the habit of coming to me from time to time during the past ten years on this subject of expert testimony, and in the majority of cases I have been disgusted at the nature of the testimony presented. Such testimony is usually positively ridiculous, particularly so in the testimony in connection with the matter of contested wills. I do not know of any class of testimony that is more foolish than in cases of this kind. All sorts of subjects are brought up which have no bearing on the matter at all; and if such a suggestion is made to a lawyer he is offended. He thinks that all such statements should be accepted without objection. Judge Abbott has called attention to one such case. Some years ago I was engaged in a case of contested will where a barber testified that he thought the testator insane because on one occasion he had forgotten his rubber overshoes in the barber shop.

In regard to expert testimony, I have long been convinced that this is objectionable in many ways. As a rule, the lawyer who calls the physician endeavors to make him a partisan to his own side rather than an expert witness. When the physician is on the stand and is cross-examined he often displays the partisan spirit in his answers. This is wrong; he should be entirely impartial in his testimony, no matter if in the cross-examination his answers would appear to be against the side that calls him.

DR. A. C. BRUSH: There is one aspect in criminal cases that has never been sufficiently brought out. I refer to the circumstances under which the expert sees the criminal. He sees him after the commitment of the crime, when the victim of paranoia, feeling that his enemy is "removed," has quieted down, and is more rational; or, again, the fear of impending punishment is sufficient to recall him to a more rational state only to lose his reasonable manner after the stimulation is removed; or, again, while imprisoned he may be animated by a feeling that he is safe from his enemies, and is quieter under these circumstances; or his counsel may have visited him in order to make up his case, and this counsel, who knows more on the subject of insanity than is commonly believed, coaches him in regard to it.

In regard to expert testimony, when an expert is put upon the stand he is often called upon to answer questions about mythical personages or characters from the Bible until he is thoroughly tired out, and then is required to answer an intricate hypothetical question. Under these circumstances he sometimes answers quite differently from what he would do if he were more cool and collected.

THE DIAGNOSIS AND TREATMENT OF ACUTE INTESTINAL OBSTRUCTION.[1]

BY J. A. GOGGANS, M.D.,
OF ALEXANDER CITY, ALA.

I BELIEVE that it is now generally conceded that more rapid strides have been made in abdominal surgery during the past few years than in any other department of our art. Still, we have not arrived at perfection in operative technic, nor have we exhausted the field so completely in point of variety of pathologic conditions that we can say that the abdominal surgeon does not still meet with cases that are more or less unique. In order that the science and art of surgery may be of the greatest utility to humanity, the surgeon should report all of his important unusual cases, especially if the results have been unsuccessful. The following case will illustrate very forcibly the importance of making a correct diagnosis and instituting proper treatment in all cases of obstruction of the intestines.

Mr. C., aged sixty-five years, married; duration of sickness, seven days. I saw him on the fifth day in consultation with Dr. Harlan. Pulse, 100; temperature, 101° F.; recurring attacks of pain in the abdomen, followed by vomiting. He had taken several one-half grain doses of calomel, and enemas of warm water had been given, but the bowels had not moved. The abdomen was not much distended, and the vomited matter consisted mostly of water. There was not the least tenderness in either inguinal region.

A diagnosis of acute intestinal obstruction was made and immediate laparotomy advised, but the patient asked that the operation be postponed for twenty-four hours, to await developments. At the end of this time the patient's condition was much worse. The pulse was then 120 per minute, the temperature 102° F., and there was more pain and vomiting. Laparotomy was performed under ether, a median incision four inches in length being made. A loop of much distended intestine protruded, and this was first punctured with an aspirating needle, and then was followed in the direction of increasing congestion until the seat of obstruction was found at the internal abdominal ring. Considerable force was necessary to dislodge the gut, and it sustained a laceration half an inch in length at the point at which it was adherent. This was closed by a few Lembert sutures. The abdomen was then closed with silkworm-gut sutures. The time occupied in performing the operation was twenty minutes. The patient rallied a little, but died six hours later.

---

[1] Read before the Jefferson County Medical Society.

As will be seen, this was no triumph of surgery. I report it, however, on its merits, believing that much may be learned from it. It serves, at least, to illustrate the symptoms of acute intestinal obstruction, as well as the extreme danger of delay in performing laparotomy after the diagnosis is evident. An experienced surgeon should be able to make a diagnosis within a few hours. The patient is suddenly seized with pain in the abdomen, which is paroxysmal in character, and is soon followed by vomiting. He soon becomes prostrated from shock, and knows that he is seriously ill; constipation is obstinate. In fact, the symptoms of intestinal obstruction are simply those of strangulated hernia.

When called to a patient presenting these symptoms we should first see whether there is a hernia; we should also exclude cancer of the rectum and impacted feces before coming to the conclusion that the obstruction may be due to bands, intussusception, volvulus, or, perhaps, to distension from gas or fluids. After making the diagnosis, the location of the obstruction should be found, if possible, and I am firmly of the opinion that this can be done with much more certainty than was formerly supposed.

The gynecologist of to-day, as well as the general surgeon, should be especially interested in this subject, for it is stated on good authority that perhaps one-half of the deaths following laparotomies are due to acute intestinal obstruction. We must look at these cases from this standpoint. The death rate from laparotomy for intestinal obstruction is, perhaps, seventy-five per cent, and without the operation, about one hundred per cent. Therefore, the operation is still justifiable. But why such a high rate of mortality after laparotomy for this condition, when the death rate from other abdominal operations is so astonishingly low? There can be only one answer, and that is *delay in operating*. It demands abdominal section for its relief just as soon as the diagnosis becomes manifest, and before the bowels become inflamed and distended. The surgeon, however, is generally called in late, and I am impressed with the belief that if many such patients were operated upon only under local anesthesia, and perhaps only an artificial anus made, the death rate would be diminished. The cause of the obstruction may be removed subsequently.

Nearly every physician or surgeon is competent to open the abdomen, but the exact mode of finding and relieving the point of obstruction is an undertaking much more difficult to accomplish. I would recommend the following plan as the one fraught with the least expenditure of time and danger to the patient: In the first place, it is reasonable to suppose that the coils of intestine which are most distended and congested will be the first to present at the incision after the peritoneum is cut through. The most congested coil should be followed in the direction of its increasing congestion, and the seat of obstruction will usually soon be found. If this method fails to locate the obstruction, the hand may be introduced to explore for it. To pass the intestine through the fingers takes much time at the expense of shock to the patient. I would warn against allowing a patient to leave the operating table with a greatly-distended abdomen. If this is done, the operation is incomplete and shock will surely follow. In fact, the cause of obstruction may be the great distension; consequently, I would, in all cases of laparotomy for intestinal obstruction, when there is much distension from gas or fluids, incise the intestine transversely and allow the contents to flow away as rapidly as possible, and then close the incision with a double continuous suture.

CLINICAL LECTURE.

THE TREATMENT OF ENDOMETRITIS; ABDOMINAL HYSTEROPEXY.[1]

BY CHARLES GREENE CUMSTON, M.D.,
OF BOSTON;
ASSISTANT PROFESSOR OF SURGICAL PATHOLOGY IN THE MEDICAL DEPARTMENT OF TUFTS COLLEGE; CORRESPONDING MEMBER OF THE ASSOCIATION OF GENITO-URINARY SURGEONS OF FRANCE, ETC.

THE first case that I wish to show you this morning is that of a young woman, single, of some thirty years of age, whom I curetted four days ago for an endometritis of some two-years' standing. The history of this patient is briefly, as follows: Three years ago she had a criminal operation performed on her for pregnancy of about two-months' duration. According to her statement, she had no unfortunate complications following this operation, although ever since that time she had noticed a yellowish mucous discharge from the vagina. She had always menstruated regularly, although she is now apt to be a few days late. The menses are rather abundant, and, since the criminal operation, have given her a certain amount of pain, so much so, that she has been obliged to give up her work, which was that of a servant.

---

[1] A clinical lecture delivered at the Deaconess Hospital.

The patient was found to be highly hysterical, and, as no satisfactory examination could be made without narcosis, ether was given, and the following condition found: The uterus was enlarged in physiologic anteversion. There is a very small laceration of the cervix, but not sufficient to justify an operation for its correction. On the left side the ovary was slightly enlarged, still it did not appear to me of sufficient importance to justify an exploratory incision in the posterior cul-de-sac or its removal. Consequently I only scraped the cavity of the uterus and shall wait and see what result this operation may have upon the patient. The curettement for the endometritis, which in this case was distinctly due to infection of the uterus at the time the criminal operation was performed, will probably do away with all the symptoms of which the patient complained, namely, pain and copious menstruation.

While there is nothing particularly interesting or remarkable in this case, I wished to show it to you and to consider the treatment of chronic endometritis, because it is one of the most unsatisfactory diseases of the uterus to treat, for, if not properly carried out, and if the after-treatment is not perfectly precise and closely looked after, the result of your operation will be absolutely *nil*, and after a short time your patients will be just as badly off as they were before you undertook to treat them. In the first place, to perform a curettement properly, it is absolutely necessary to perform the operation correctly, and, before passing to the next patient, I wish to say a few words regarding the operation and the after-treatment of the patient. The operation is condemned by many, but it also has its upholders. It is evident that a short time ago it was performed for almost every symptom that a woman could present in her genital organs, and was certainly very much abused, but now the indications appear established, and we know much better when to resort to it.

In endometritis the mucosa of the uterus is the seat of disease at the beginning, and, if it is allowed to continue for any length of time, the lesions will little by little penetrate into the body of the uterus, that is to say, into the middle of the walls, and it is precisely this infiltration that will render not only the diagnosis somewhat difficult, as in long standing cases it might be taken for epithelioma, but the result of the operation is not so good. Curettement, as you know, consists primarily in removing the fungoid endometrium, but this is simply a part of the treatment of endometritis, and, if you only curette the uterus, the results will be poor. As in the treatment of infected cavities, disinfection is what you aim at, and this is the end attained by curettement. In order to be able to disinfect the uterus, the organ must be first dilated and afterward cleansed by a solution of chlorid of zinc, or, what I consider better, equal parts of glycerin and creosote. In performing curettement you must employ complete narcosis, because you must obtain an absolute relaxation of the patient in order to do it properly. I always place the patient in the dorsal position, with the legs held back on the abdomen by an assistant standing on each side. The next thing to do is to thoroughly disinfect the vagina with nail brush and green soap, but one point on which I would insist is that you must be careful not to brush too hard, or otherwise you will produce abrasions in the vagina, and this may give you trouble in the after-treatment. After the vagina has been thoroughly brushed, a douche should be given, either of sublimate, 1 in 4000, or of a one-per-cent. solution of lysol or creolin. It is needless for me to say that any operation on the genital organs of the female requires that the parts should be shaved thoroughly before the operation, because the hair on the pubis and vulva makes excellent culture grounds for infectious organisms. You next introduce a speculum, or, what is still better, a simple posterior vaginal retractor, which will bring the cervix quite sufficiently into view, and then grasp the latter with a pair of stout tenaculum forceps. When you do this be sure to include a considerable amount of tissue between the teeth of the instrument, in order that it may not slip and tear the cervix. Personally, I usually catch the anterior lip of the cervix, although many operators think it better to catch the posterior one. If there are no periuterine lesions, you may draw the cervix down to the vulva, but if any inflammatory condition is present above, you simply steady the cervix by your forceps, and by simple retraction of the posterior vaginal wall you will be able to see sufficiently well to curette with the uterus in place. After the forceps have been applied to the cervix you proceed to dilate. There is considerable importance in selecting the proper instrument for this. When there is a narrow cervical canal, it is better to begin by passing a few Hegar's sounds, in order to render the canal patent and sufficiently large to allow of the introduction of the blades of a metallic dilator. If, on the contrary, the canal is sufficiently open, the dilatation with Hegar's sounds will not be necessary.

You will see Goodell's dilator used, or some modification of it, in almost all of the hospitals. Personally, I consider it far too powerful to use, and I know of no better instrument than the old three-bladed dilator described and employed by Scanzoni many years ago, which I find answers every purpose. When closed the blades of this instrument are not very much greater in circumference than an ordinary uterine sound, and it can be introduced with great ease into the canal, and by a little pressure the three blades separate, and dilatation is very easily accomplished without lacerating the tissues of the cervix. When the canal has been dilated sufficiently to introduce the curette, you should proceed by scraping first the anterior wall of the uterus, then the posterior wall, and then the sides, and you should finish by removing all diseased tissue around the orifices of the tubes. All this should be done methodically, or else you will leave a large amount of diseased mucosa in the uterus, which will simply be the starting point of a new endometritis. I have also a word to say regarding the curette. Nearly every operator has invented a curette, which he considers superior to any other, but in my opinion no instrument of the kind has been devised that is superior or as good as that of Recamier. This is long and narrow, and for this reason is easily directed into the corners of the uterus, and can reach and remove all of the diseased mucosa.

The after-treatment of curettement for endometritis is of great importance. The uterus having been thoroughly irrigated with lysol solution, and having been carefully swabbed out with a tampon wet in glycerin and creosote, equal parts, the dressing is proceeded with. In order to drain the cavity the first thing necessary is to keep the orifice dilated and not allow it to close up. For this purpose iodoform gauze is largely used, the uterus being completely packed by some operators, while others simply drain it by introducing a few strips. I have used gauze drainage in some twenty cases, and I am free to confess that nearly all of them did poorly. The gauze appeared to block up the uterine orifice, and the secretions stagnated in the cavity. Of this I am sure, because two or three of the patients had an elevation of temperature a day or two after the operation, and when the gauze was removed and intra-uterine douches were given, a large amount of bloody liquid was washed away. In another series of cases I did not make use of drainage, but simply kept the vagina aseptic, dispensing with other dressing, but it appears to me in every way more surgical to drain and to drain *surgically*. For this reason, as well as to keep up a good dilatation, I insert two small rubber drains, which have previously been sterilized by boiling in a 1-in-1000-corrosive-sublimate solution, and carry them up to the fundus of the uterus and allow them to protrude from the external orifice of the cervix for about six centimeters. I then pack the posterior cul-de-sac of the vagina with iodoform gauze, then the anterior cul-de-sac, and finally the entire vagina, leaving the two drains protruding about two centimeters from the vulva. I thus obtain direct drainage from the uterine cavity. Over the drains are placed several sterile gauze pads, which are changed, as in any other case of surgical drainage, as soon as they are soiled. The patient's urine is drawn every eight hours during the time that the drains are left in place, and she is allowed to sit up in bed on the day following the operation. By allowing your patients to sit up, you will produce an excellent inclined plane, which will allow all contained secretion to immediately run off, and as the drainage tubes are sufficiently large, the drainage of the uterus, I believe, is complete. Every day ten cubic centimeters of peroxid of hydrogen is injected through one tube into the uterine cavity, and this keeps the tubes as well as the uterus clean. According to the case, I leave the packing and drainage tubes in place for eight or ten days. I then remove them, thoroughly irrigate the vagina in the morning for three or four days, and usually the patient will be perfectly well after that.

If one is dealing with a chronic or septic endometritis, I think it well to leave the drainage tubes in place for at least fifteen or twenty days, and, if an intelligent nurse who understands the principles of surgical asepsis has charge of the case, and she is given necessary directions, infection of the uterus from without need never be feared, and your patients will be benefited by the operation.

You see in this case that the drainage tubes are protruding about three centimeters beyond the vulva, and it is now four days since the operation and all discharge from the uterus has ceased. I shall remove the tubes at the end of a week, and I think the patient will go home completely cured of her malady after the expiration of ten or twelve days.

The patient that I now show you is a woman, sixty years of age, upon whom I performed abdominal hysteropexy just seventeen days ago, and as the case has presented some interesting features, and as the indications for performing this operation are very often misunderstood, I desire to speak at some length regarding it. In the first place, you will see by the chart that the temperature went up to nearly 38.5° C. on the evening of the operation; that on the next day it was about 38° C., and that on the second day it rose again to nearly 38.5° C. The elevation of temperature after abdominal operations, when occurring on the succeeding two days, is usually not of much importance. The most important point to consider is the pulse. In the case of this patient, the pulse was 130 on the night of the operation, and the next day it still ranged at about 115 beats a minute. This pulse rate occasioned me some alarm, because it is a far too frequent beat, and would indicate infection of the peritoneal cavity. After the second day, however, it dropped to about ninety, and remained there, and the patient, as I have told you, made an uneventful recovery. Rise in temperature and a very rapid pulse rate is exceptional in uncomplicated cases, but in the present instance this unusual occurrence can be explained, I think, by the fact that for several days previous to the operation the patient had a morning diarrhea, there being as many as six or seven liquid movements during the forenoon; and then when the abdomen was open, the bowels, which were in a subacute inflamed condition, were irritated by the manipulation necessary to suture the uterus to the abdominal walls, and this provoked a slight irregularity in the temperature and pulse.

Regarding operations in general on elderly people, I would say that unless the patient is in excellent condition one should always be prepared to meet any indications of shock that may occur. A hypodermic syringe containing one-fiftieth of a grain of strychnin, in solution, should be at hand to counteract symptoms of collapse, and, what is most important of all, preparations should be complete for the administration of artificial serum, either directly into a vein or subcutaneously. I will give you a few formulæ for the preparation of this serum. The solution recommended by Hayem is probably the best for injections of large quantities, for the reason that its composition is very similar to that of the blood serum. It is as follows: Chlorid of sodium, five grams; sulphate of sodium, ten grams; boiled water, one liter. Another very excellent solution, recommended by Chaleix-Vivie and Audebert, which they say will give very encouraging immediate results, is chlorid of sodium, seven grams; glycerophosphate of sodium, four grams, and sterilized water, one liter. Chéron prefers a more concentrated serum, made by combining pure carbolic acid, two grams; chlorid of sodium, four grams; phosphate of sodium, six grams, and sulphate of sodium, eight grams, with boiled water, 100 grams. This condensed solution, in which the phosphate of sodium has been introduced on account of its action on the nervous system, may be injected in doses of fifteen to thirty grams, and may be repeated several times a day and continued for several days. In acute anemia following hemorrhage, it is highly recommended. The important thing to remember is that the solution must be absolutely sterile. It should be boiled, a small amount of chlorid of sodium being added, on account of the concentration which results from the evaporation of the water during boiling.

I will explain to you in a few words why I performed abdominal hysteropexy upon this patient. She came to the dispensary early in the spring of 1896 with a prolapse of the uterus, although this was not very marked, the cervix hardly appearing at the vulva. I did not wish to subject her to a very severe operation. I thought that a plastic operation on the anterior vaginal wall, with a perineal operation, would be sufficient, and this was performed, with the result that she was up and about at the end of three weeks feeling perfectly well. The condition remained excellent until the middle of last summer, when she was out walking and caught her dress on some obstacle and fell on her back. This produced considerable strain, and a few weeks later she noticed that the uterus, which up that time had not given her trouble, had begun to fall again. I saw her again in October and found that the uterus and vaginal walls were again prolapsed, although not to any such degree as before the operation, and, as I was afraid that little by little the uterus might return to its former position, I advised her to have the abdominal operation performed, to which she agreed.

Abdominal hysteropexy is a very good operation under certain conditions, and, in my opinion, under these conditions only. In the first place, the patient must have passed the child-bearing period, because in many cases in which the operation has been performed on young women who have afterward conceived, the pregnancy has been interrupted at the third or fourth months; or when it is gone to term in many cases the labor has been rendered difficult on account of the adhesions existing between the uterus and abdominal wall, and it has been necessary in quite a number of instances to resort to some of the major obstetrical operations in order to deliver the child. This is a sufficient reason why the operation should be rejected in the case of all women who can still have children. Another contraindication is when the uterus and adnexa are bound down by adhesions resulting from inflammation. Under these circumstances the operation would be rendered extremely difficult and probably impossible and might be the means of setting up anew all the former inflammatory troubles. I would also say that when abdominal hysteropexy is not combined with a plastic operation on the vaginal wall, in all probability it will be a complete failure. When this combination is carried out I consider it the very best operation in use for prolapse of the uterus in elderly women, and I know of nothing to take its place. Regarding vaginal hysterectomy for prolapsus, I think that it is an imperfect operation for the relief of the condition, and is only indicated when the prolapsed uterus contains a fibroid tumor, and then it is performed, not for the prolapsus, but for the neoplasm. There is one indication for vaginal hysterectomy for prolapsus, and that is when the organ has become strangulated and reduction is impossible. In this case, in order to avoid gangrene of the genital organs from the cutting off of the vascular supply by strangulation, vaginal hysterectomy is absolutely indicated, and is probably the only operation that will save the patient.

The after-care of patients who have undergone abdominal fixation of the uterus consists principally in keeping them quietly in bed for at least three weeks. The sutures may be removed at the end of eight or ten days, and if all goes well the patient may be allowed to sit up at the end of twenty-one days. Although the abdominal incision for this operation need only be six or seven centimeters in length, the possible occurrence of hernia should always be considered, and the abdominal walls supported by a binder for a year or eighteen months.

An interesting feature of this case was the extreme amount of gas in the bowels, which gave the patient a great deal of pain. To overcome this she received an enema of soap suds and an ounce of turpentine every time she was distressed, and this brought away the gas and afforded relief, although during the first four or five days after the operation she received as many as five or six enemas in the twenty-four hours. Another excellent treatment for the relief of gas in the intestines following abdominal operations is the introduction of a large tube some eight or ten inches into the lower bowel.

The feeding of patients after abdominal hysteropexy is practically the same as after any abdominal operation. The diet should consist chiefly of milk, to which may be added some lime water and gruel. Champagne is very efficacious in relieving the nausea. I can also very highly recommend the compound tincture of cardamon, ten drops of which may be given on a lump of sugar every two hours. The bowels should be moved by a saline forty-eight hours after the operation, or even earlier if there is any particular indication for it.

MEDICAL PROGRESS.

Etiology of Cancer.—RONCALI (*Centralbl. für Chirurgie*, No. 50), in a paper read before the Eleventh Congress of the Italian Surgical Society, held in Rome, October 26–29, 1896, thus sums up the present knowledge of the etiology of cancer:

1. In the cell protoplasm and connective tissue of malignant new growths are found bodies which are not of cellular origin, but come from the outside world.
2. These bodies are morphologically similar to the so-called coccidia which different investigators have found in the cells of epitheliomata and sarcomata.
3. These bodies which are found in cancer are morphologically identical with blastomycetes which are found in animals after they have been inoculated with pure cultures of organized ferments.
4. They resist acids and alkalies exactly as do the inoculated blastomycetes.

5. They occur only in malignant growths.

6. In new growths in men they are found in certain places, as in the periphery, where growth is still active, and not in the middle where the elements are already degenerated. They are situated either in the protoplasm of the cells or between the fibers—only exceptionally in the nuclei.

7. They stain in the usual way, and can often be obtained from malignant tumors of men and animals and grown in a pure culture.

8. Such pure cultures are always composed of blastomycetes, and when inoculated they press into the cells and between the fibers, producing the same appearances as in the tumors of men and animals from which they were isolated. These bodies show the reaction of cellulose exactly as do the blastomycetes which have been injected into the tissue of an animal. This is a proof that they do not arise from the degeneration of the cells of the cancer.

9. Certain blastomycetes produce in the animals experimented upon changes of a neoplastic, not inflammatory, character.

In spite of these results Roncali did not consider that the etiology of cancer was definitely determined. First, it would be necessary to inoculate with blastomycetes obtained from a malignant tumor of a certain species of animal another animal of the same species; and to obtain in the animal inoculated the same malignant new growth, as existed in the other animal.

The same subject was discussed by Maffucci and Sirleo who had examined twenty-four malignant tumors (carcinoma and sarcoma) and obtained from them various sorts of blastomycetes which they had injected into animals. They formed conclusions in the main similar to those given by Roncali. They found blastomycetes especially in ulcerated malignant tumors and strongly suspected that they should be looked upon as the result of a secondary infection. In general, they did not oppose the opinion that cancer and sarcoma might be caused by blastomycetes, but as yet this has not been demonstrated by experiments.

A Rare Case of "Hemorrhoids" of the Prostate.—Krauss details in the *Wien. klin. Wochen.*, No. 28, 1896, an unusual case. The urine of the patient, a man fifty-eight years of age, contained an appreciable quantity of blood. A blood clot was always voided before the beginning of urination, especially when the bladder was distended with a large amount of urine. A normal stream usually followed the escape of the blood clot, or a quantity of blood-stained urine was voided followed by an intermission, after which blood clots were passed, followed again by a normal stream of blood-stained urine. The prostate gland was undersized, and cystoscopic examination of the bladder gave only negative results—cystotomy was performed and revealed a continuous flow of blood from the anterior part of the neck of the bladder toward the posterior wall of the bladder. In the neighborhood of the neck of the bladder distended veins and even varix were visible. On digital examination the mucous membrane of the neck of the bladder was found to be normal and smooth, so that the hemorrhage must have come from the portion anterior to the internal vesical sphincter, or, in other words, from the region of the prostate. The Paquelin cautery was applied to the part adjacent to the internal orifice of the urethra. After complete cauterization the hemorrhage from the prostate ceased and complete recovery ensued.

A Point in the Early Diagnosis of Coxalgia.—Alexandroff (*Revue de Therapeutique*, January 15, 1897), in the early diagnosis of hip disease, lays especial weight upon the two signs of atrophy of the muscles and hypertrophy of the subcutaneous adipose layer. He attributes to this latter symptom a great value, for it may exist when all other symptoms are wanting, and in its absence the diagnosis of coxalgia can be rejected. It can be determined by lifting folds of the skin and subcutaneous tissue upon the thigh and buttock, as well as upon the leg and foot. It will be found that on the affected side the fold is from one to four m.m. thicker than on the well side. A special apparatus, called the adipometer, which resembles a pair of calipers, has been designed to measure these folds.

THERAPEUTIC NOTES.

To Remove Papillomata of the Vulva.—Manciere (*Centralbl. für die Gesam. Ther.*, January, 1897) recommends mixture of flexible collodion five parts, and salicylic acid two parts, of which a single drop is to be applied to each wart. At one treatment eight or ten may be touched in this manner. On the following day the application is made to a number of others, and also to those previously treated. This is kept up daily until all are gone. The collodion does not affect the healthy tissue.

The Treatment of Painful Cystitis in a Woman by Vesical Curetting.—Camero reports (*Revue de Therapeut.*, February 1, 1897) twenty-nine cases in which this treatment was carried out through the urethra without distending this passage. After the curetting a catheter was left in for two or three weeks. A favorable result was obtained in two-thirds of the cases. In many patients the cystitis is located in the trigonum, and is therefore accessible for curetting. If this treatment fails, suprapubic cystotomy may be performed.

Ichthyol Internally.—Gunsbourg tells in the *Revue de Therap.*, February 1, of the internal administration of ichthyol to seventy patients in his gynecological clinic. The sulphichthyolate of ammonia was the form of the drug employed, and it was given in pill form to the amount of two to three grains per day. The drug had a favorable influence on the dyspepsia, complicated by constipation, which is so common in patients of this class. Defecation became normal and occurred daily. The appetite improved, abdominal pain grew less or disappeared altogether, while in many patients menorrhagia was also cured. No unpleasant effect whatever followed this treatment.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

PUBLIC SCHOOLS AS PERPETUATORS OF INFECTIOUS DISEASES.

IF any decided advance is to be made in suppressing contagious diseases among children, quarantine regulations in schools would seem to be a necessity. No better demonstration of this fact need be sought than is contained in the report of the first day's work of the school inspectors recently appointed by the New York Board of Health. Through the discoveries of these officers 140 children were found unfit for association with their schoolmates, and sent to their homes with notes to their parents informing them of the children's condition. Among these were fourteen cases of diphtheria, three of measles, and one of scarlet fever; thirty-five cases of contagious eye diseases, three of mumps, and one of croup; of parasitic diseases there were fifty-five cases where the head was afflicted, and twelve of the body; and there were eight cases of chicken-pox, and eight of communicable skin diseases.

When one realizes what a focus of dissemination each one of these cases may become in the close air of a crowded schoolroom the wisdom of the health board in instituting this system of inspection is worthy of all praise. The enormous diminution in the number of infectious diseases such precautions must bring about can be appreciated only by those who know how many mild cases of children's diseases are never seen by a physician. These will now be brought to light by the inspectors who will investigate the cause of absence from school, of children sick at their homes.

The reports of the inspectors seem to justify the claim made by Sanitary Inspector Lynd as the result of his personal investigations, that about two-thirds of all cases of scarlatina and diphtheria and all unusual and severe outbreaks of these diseases can be traced to schools. Under the old régime not only was it the frequent experience to find a disease well advanced in the contagious stage and already communicated to other children of the school before it was detected by parent or teacher, but also in families containing more than one school-attending child, another apparently healthy child was carrying the contagion to other classes or schools. Moreover, children still in a stage of infectious convalescence were quite apt to be returned to school and innocently become the foci of greater or less epidemics. It is to be hoped that the duties of the inspectors will not be confined to sending children home and writing notifications thereof to the Board of Health but that questions of hygiene and sanitation may engage their attention. The condition of plumbing, the practice of the teachers in regard to ventilation, the use of washbowls and towels in common, and last, but not least, the unwashed and offensive condition of some of the children. It is reported that one of the teachers begged the inspector who examined her class to send them all home; they were "so filthy to her eyes and nose that they made her sick."

REQUIREMENTS OF HEALTH BOARDS.

IN the issue of the MEDICAL NEWS, February 13th, appeared an announcement headed "The Minimum Requirements of the Pennsylvania Board of Health for the Production of Vaccine Virus, Antitoxin, Tuberculin, and Other Animal Products Used in Medicine." In this certain rules appear, followed by the statement that "no vaccine virus or other animal products will be approved by the State Board of Health of Pennsylvania unless propagated in accordance with the provisions of the aforesaid rules."

The methods of production and distribution of products, the character of which so intimately concerns the health of the people of a State, may well be the care of a State board of health. In a similar way the Boards of Health of New York and other cities have already exercised their authority to prevent the sale of certain unreliable antitoxins. Still, such extension of the authority of a health board is of comparatively recent origin, is not guided in its method by a long series of precedents, and therefore every instance becomes in itself a precedent of importance. So much the more care should therefore be taken that no unnecessary regulations be made; that all those made be well considered, and that in particular no decrees be promulgated about the wisdom of which there is not general agreement among competent judges.

The requirements of the Pennsylvania Board of Health, as stated in the above-mentioned announcement, do call, however, for the adoption of many measures which can in no way be considered necessary. Thus, for the production of the best vaccine it is not necessary that the walls of the stable should be of either painted boards or whitewashed plaster; it is only advisable that they should be tight and easily cleaned. The floor may well be of something else than the prescribed concrete. Animals less than the required three months of age may produce vaccine of the best quality; it is not necessary that the food should contain grain, when, as sometimes happens, the animal is a milk-fed calf. In the fifth regulation it is stated that "stables should be liberally bedded with clean white straw, hay, dry sawdust, or German peat. The latter, from its great absorbent power and antiseptic action, is highly commended." Bedding may well be of other material—excelsior, for example. German peat has not been shown to have any antiseptic action. In the same regulation it is observed that "in the winter term a temperature of 62° F. is correct." Is this a necessity, or would 60° or 65° F. be acceptable? In the sixth regulation it is stated "that animals should be . . . . washed thoroughly, if necessary, in such a manner as to render them practically *antiseptic* before operation." It may be supposed that the author meant that the skin should be made aseptic, but this requirement is also unnecessary, and is, in fact, impossible of accomplishment. The same is true of the requirement that "the skin of the animals should be kept sterile at all times." The regulations say that the "walls of the operating room shall be washed with bichlorid of mercury *from time to time.*" Rules so inexact can hardly win respect.

These do not by any means exhaust the list of inadvisable regulations, but they do emphasize the obvious conclusion that before such a list of requirements is issued by an authoritative body it should be carefully revised, and that the really valuable regulations, such as the one in the present list, that "every package of virus must have on it the name and address of the propagator and the date when the virus was taken," should not be covered up by a mass of other directions, impracticable in some cases, because of their misdirected minuteness, and objectionable in others, because of the impossibility of carrying them out.

The requirements for the production of antitoxin, tuberculin, etc., are less fully given, but are stated to be similar to those for the production of vaccine. The total difference in nature between tuberculin and mallein—the toxic products produced by the growth of the tubercle and the glanders bacillus—the curative serums obtained from the blood of animals and vaccine, from the serum and pulp of skin vesicles, do not seem to be appreciated by the authors of the circular.

It is eminently proper for health boards to require that samples of antitoxin, vaccine, and other bacterial and animal products shall have stamped on them the name of the dealer or manufacturer, their strength, and the date upon which they were tested or produced. It is also advisable that samples should from time to time be bought in the open market and carefully tested. It would seem, however, that great caution should be observed in making minute directions for the preparation of these products, because methods are constantly changing. Even assuming that the regulations promulgated are at the moment of their adoption the very best possible, yet before their distribution can be accomplished they may have already been superseded by better.

ECHOES AND NEWS.

A Princess as Trained Nurse. — Princess Frederick Leopold of Prussia is undergoing a regular course of training as a hospital and field nurse.

The College of Physicians and Surgeons of Chicago.—This institution has recently become legally the Medical Department of the University of Illinois.

The New York Colored Home and Hospital.—This institution has sold its property at the corner of Sixty-fifth street and First avenue for $210,000, and will secure a new site in the uptown suburbs.

Letters of Asylum Inmates.—A bill is pending before the Michigan legislature giving the inmates of insane asylums the right to correspond by letter with their friends of the outside world, unmolested by the officers of such asylums.

Hospital Property Exempt from Taxation.—A bill has been introduced in the New York legislature exempting from taxation that part of the New York Ophthalmic Hospital property that is rented out for the purpose of raising money to support the hospital.

A Victim of Cigarette Smoking.—A young man, aged twenty, died recently in Bellevue Hospital from nicotin poisoning. He was a victim of the cigarette habit, and frequently smoked, according to his father, as many as sixteen packages of cigarettes in a day.

Appointments of English Physicians. — Mr. Frederick Treeves, F.R.C.S., has been appointed by the Duke of York Surgeon-in-Ordinary to His Royal Highness, and Dr. A. R. Manby, Surgeon-Apothecary to His Royal Highness' household at Sandringham.

Ambulance Kills a Horse.—A Bellevue Hospital ambulance, in which were two patients, recently ran into a horse attached to a wagon. The shaft of the ambulance penetrated the shoulder of the horse and killed it instantly. The patients were shaken up somewhat, but sustained no injury.

The Chicago German Medical College.—The German Consul at Chicago having reported to the home government unfavorably on the Chicago German Medical College, and its alleged sale of diplomas, the Prussian government has ordered that all persons publicly exhibiting a degree obtained from that institution are to be prosecuted.

Improved Tuberculin.—Prof. Koch publishes in the *Deutsche Medicinische Wochenschrift* the result of his latest experiments in the treatment of consumption. He says that he has greatly improved his tuberculin. The bacilli which form the basis of the lymph are now destroyed as living organisms, while their curative properties for the early stages of the disease are retained.

Free Beds for Sick Doctors.—The Trustees of the Philadelphia Polyclinic and College for Graduates in Medicine have set aside one room in the Polyclinic Hospital for the use, free of charge, of any member of the Mutual Aid Association of the Philadelphia County Medical Society, whose financial circumstances require such concession in regard to hospital charges.

New Hospital for Harlem.—The city authorities have decided to erect a modern hospital in Harlem at a cost of $300,000. The site for the new hospital is not yet selected. One location proposed is on the northwest corner of 124th street and Madison avenue. The present hospital grounds at the foot of East 120th street have also been mentioned.

Opposition to Board of Health Inspectors.—Dr. R. M. Leverson, representing the International Homeopathic Society, is reported to have said in discussing, before the mayor, the provisions of the charter of the Greater New York relating to communicable diseases: "I would take a revolver and shoot down the health officer or policeman who would undertake to break into my house."

Fire at the Manhattan State Hospital.—The damage done by the recent fire in the Manhattan State Hospital for the Insane on Ward's Island is estimated at about $100,000. The success with which all the patients were removed from the burning building is an instructive comment on the organization and discipline of the institution. The patients whose accommodations were destroyed have been distributed among the branch hospitals.

Small-Pox in New York.—The Bureau of Contagious Diseases is fighting a small wave of small-pox which started among the Park row lodging-houses two weeks ago. Since that time eleven cases have been discovered. The disease has broken out again in the New York Hospital. All the victims and people exposed to the infection are accounted for and kept under careful supervision. The corps of vaccinators has been kept actively at work.

Bubonic Plague Attacks the British Troops.—A special despatch from Bombay says that the plague has broken out among the British troops at Calaba. According to the official list published in Bombay, the total number of deaths in that city for the week ending April 2d was 1111. Of these, 455 were due to the bubonic plague. During the last fortnight five cases of Europeans attacked by the disease have been officially reported. Two of these have proved fatal.

Pathological Society of Philadelphia.—The annual conversational meeting of the Society will be held in the Upper Hall of the College of Physicians, northeast corner Thirteenth and Locust streets, on Thursday, April 22, 1897, at 8.15 P.M. Dr. Ludvig Hektoen, Professor of Morbid Anatomy in Rush Medical College, will deliver an address, entitled "Segmentation and Fragmentation of the Myocardium." After the meeting a reception will be tendered Dr. Hektoen at the University Club, 1316 Walnut street. A cordial invitation is extended to attend the meeting and the reception.

Temporary Control of the Insane in New York.—The Medical Society of the County of New York, the New York Neurological Society, and the Society of Medical Jurisprudence are seeking an amendment to the insanity law which has been in operation since July 1, 1896, providing for the temporary commitment of dangerous or violent lunatics for five days upon the sworn certificate of two authorized medical examiners in lunacy, pending the outcome of the legal proceedings for final commitment. Dr.

P. M. Wise, chairman of the Lunacy Commission of the Senate, has returned it without his approval, saying that the present law had not been in operation long enough to attempt to change it. The bill is not without friends, however, for Senator Ford has promised to father the amendment in the Senate and urge its passage in the Assembly.

Duties on Mineral Waters.—Petitions to Congress often receive scant, if any, consideration, but it is to be supposed that favorable attention will be accorded by the United States Senate to the petition which the leading medical men of New York and other cities are presenting relative to the exorbitant, and in some respects prohibitive, duties proposed for mineral waters in the Dingley tariff bill. Mineral waters should receive special consideration by Congress, as they are valuable and necessary agents of hygiene and medicine. In fact, in previous tariff revisions Congress distinctly expressed itself in favor of free mineral waters, and as a result they have been on the free list over a quarter of a century. From the standpoint of the profession, no change in the conditions has occurred which would warrant a high duty on these products of nature.

A Keen Swindling Game.—Swindlers have been operating in Passaic, N. J., for the past week, and are said to have fleeced a number of physicians. A man and a boy about sixteen years old worked the game. The man would drive in a buggy to the residence of a physician, and summon him hurriedly. The boy always accompanied the man. His clothes would be very dusty, and he would be carried into the office of the doctor. There the man, who was evidently a Hebrew, would explain that the boy had been run over, and request an examination. When the doctor found that the boy had not been injured, although he complained of pains in the back, the man would ask the charge. The fee was generally $1, and in payment the man tendered a check for $5 on the First National Bank, drawn payable to Wallace Lawrence. The doctors usually cashed the check, giving $4 in change, and then, with apologies for disturbing him, the man and boy drove off. When the checks reached the bank, they were returned as worthless.

An Epidemic of Hiccough.—Miss Lucy Marshall of Centralia, Mo., began to hiccough last Christmas Day, and has been unable to stop since, although the best medical advice has been obtained. She is unable to sleep longer than a few minutes at a time, and may die if not relieved soon. About two weeks ago her younger brother began to hiccough, and has continued ever since. On March 28 a younger sister commenced hiccoughing and cannot stop. The malady threatens to affect the entire family, the members of which feel much alarm.—Louis A. Levy of Jersey City was attacked by hiccough while reading a newspaper in his store on February 26th. The hiccough has continued at intervals ever since. At first the spasms recurred every eight minutes. More recently the spasms recur only at intervals of three hours, the patient being able to take nourishment and sleep in the intervals. —William Bond of Glen Cove, L. I., who has suffered from two attacks of prolonged and incessant hiccoughing, is still very weak, although the doctors have succeeded in stopping the spasms.

One of the Uses of Microbes.—Dr. De Schweinitz, in his presidential address recently delivered before the Chemical Society of Washington, said: "When milk and cream are first collected they are almost free from germs; but exposed to the air, they soon become filled with those forms of life which are perfectly harmless. If placed under suitable conditions with regard to temperature, they will multiply very readily, and the milk becomes sour, due to the formation of lactic acid produced from the sugar in the milk by one or more of these germs. If the germs present happen to be those giving an ether and ester which have a pleasant flavor and aroma, good butter results; but if they give rise to the formation of disagreeable thio ethers and esters or some amines, the butter is poor and bad. Now, by isolating different germs found in the milk, and cultivating them separately so as to discover their own peculiar product, it is possible to always make butter of the same sort and flavor by first destroying the other germs present by Pasteurization and then inoculating the cream with the particular germ desired. A number of germs have been isolated from milk which will produce good butter, and any one of them is perhaps as good as the other, the ethereal product being slightly different and more palatable to different individuals. Of course, a great many germs have been found which produce disagreeable compounds, and it is not possible to tell from their appearance simply which is a desirable plant, but it is easy to cultivate them in milk and note the results, and select the desirable plant cell. Fortunately, or unfortunately, the use of these germs has been patented, so that in the near future we may see branded upon particularly fine butters and cheese, 'patented in 1893, amended 1896, reissued 1908,' etc. May we expect soon a patented process for breathing, eating, and sleeping?"

Obituary.—Dr. John O. Bronson died March 28th at his home in Rhinebeck, New York. He was born in Glastonbury, Conn., 1827, and was educated at Yale College and the New York Medical College, in which he became Professor of Anatomy in 1857. Several years later he took a course in hospital work abroad, and at the breaking out of the war he was appointed Chief Medical Director of the Department of the Pacific, which he filled for two years. He then served until the close of the war as Chief Medical Officer of the Department of the South. He returned to the practice of his profession in New York City, and remained there until 1880, when he retired. For a number of years Dr. Bronson was interested in the development of the State of Florida. Through his influence, the Alabama, Florida, and Atlantic Railway Company was formed. It built 550 miles of railroad, and opened up the entire Northwest to the productions of Florida.—Dr. Felix Cipriano Coronel Zegarra, well known in the United States as the representative of Peru at the Pan-American Congress, died at Lima, Peru, March 29th. —Word has just been received in Brooklyn of the death from jungle fever last January in Central Africa of Dr. Samuel G. Armour, a young physician in the service of the Belgian Government. He obtained his education at the Long Island College Hospital, where his uncle, the late Dr. Armour, was Dean. Dr. Armour graduated in 1892, and was interne at the hospital for two years. About a year ago, together with a number of Americans, Dr. Armour signed contracts with the Belgian Government to go to Congo Free State. It was a part of their mission to deal with the Arab slave hunters who infest portions of that country and break up their traffic. Dr. Armour sailed from this city for Brussels February 15, 1896. He landed at Boma, a town situated at the mouth of the Congo River, and proceeded, with his companions, up the river to Stanley Pool. There they were assigned to their stations.—Dr. Joseph F. James died at Hingham, Mass., March 30th. He was born in Cincinnati in 1857. Dr. James was Professor of Botany in the Cincinnati College of Pharmacy from 1880 to 1889, and Professor of Physiology, Biology, Geology, and Botany for two years at Oxford, O. He studied medicine at Washington Columbia School, graduating in 1895. After graduating, Dr. James took a course of lectures at Guy's Hospital, London, and at London Hospital Medical School. He leaves a wife and two small children.—Dr. George B. Twitchell, one of the leading physicians in New Hampshire, and President of the Keene Humane Society, died in Keene March 30th, aged seventy-seven years. He was a native of Virginia, a graduate of the University of Pennsylvania, and served with distinction during the civil war.—Dr. F. D. Dubois, for twenty years physician at Blooming Grove, Orange County, New York, died March 30th of pneumonia, aged fifty years.—Dr. Jonathan Burtis died in Hartford, Conn., March 31st. Death was due to stomach trouble. He was born in Epsom, N. H., June 11, 1821.—Dr. Walburg Coleman, a son of the late Dr. James Coleman, died in Trenton, N. J., March 31st, aged fifty-one years. He was at one time Surgeon-Major of the Seventh Regiment, N. G., S. N. Y.

CORRESPONDENCE.

NOTE ON THE SERUM-TEST FOR TYPHOID FEVER.

To the Editor of The Medical News.

Dear Sir: I desire to record the following brief note on a case of typhoid fever in its relation to the serum-test, in the hope that a certain peculiar feature may make it of value in the statistics of some future writer.

John M., aged thirty-five years, was seen by the writer January 3, 1897, suffering from what was believed to be typhoid fever. The diagnosis was based chiefly upon the temperature range, for there were no diarrhea, spots, or nosebleed. Tenderness was present only in the right iliac fossa, which, with the absence of important typhoid symptoms, made the diagnosis of catarrhal appendicitis probable.

To settle the uncertainty I decided to have the serum-test made, so at the close of the second week of the fever a specimen of the patient's dried blood was sent to the Bacteriological Department of this city for examination. Although the department was not at that time ready for the general examination of such cases, the acting chief made two careful tests and notified me that the reaction was negative and that the case was probably not typhoid.

All fever disappeared by the eighteenth day, and, after eight days of normal temperature a mashed potato was allowed. A relapse followed, running twenty days. Still there were no diarrhea, spots, or nosebleed, and the tenderness in the right side returned. The question of catarrhal appendicitis or typhoid fever remained undecided. About the middle and at the end of the relapse dried specimens of the patient's blood were sent to the department for further examination. Both of these specimens gave a marked reaction in a few minutes.

In a paper, upon the serum-test, by Drs. Bigg and Park (*Amer. Jour. of the Med. Sciences*, March, 1897), besides a statistical study of former reports, a detailed history of four cases was given. Three of these cases had relapse, and it is a significant fact that in two of them careful examination failed to get the reaction during the first attack of one case, and was not marked save in a dilution of one part of serum to four of culture, in the second case; while in both cases, as early as the second day of the relapse, an immediate marked reaction was found in a dilution of one to ten.

It has been found that in those cases of pneumonia where leucocytosis does not take place, it is safe to give an unfavorable prognosis. It is an evidence that the forces which fight for health and life are unable to subdue the disease.

In the light of these three reports may it not be found that the absence of the reaction during the first attack will prove an important warning that nature is not preparing enough antitoxin to make a recovery safe from a relapse?

Certainly, until fuller knowledge convinces me of the contrary, I shall be particularly solicitous during the convalescence of any patient suffering from typhoid fever where this action is absent or indefinite.

I write this in the hope that future reporters will notice this feature. Very truly yours,

W. C. Cahill, M.D.

Philadelphia, March 30, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

PHILADELPHIA OBSTETRICAL SOCIETY—THE DEATH-RATE FROM DIPHTHERIA—FILTRATION BY ELECTRICITY—COLLEGE-BRED MEDICAL STUDENTS—DR. JOHN H. EGAN—THE BOARD OF CHARITIES AND CORRECTION—COMMENCEMENT OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

Philadelphia, April 3, 1897.

At a stated meeting of the Obstetrical Society, held on April 1st, Dr. H. A. Hare read, by invitation, a paper on "The Value of Quinin in Labor." Dr. Hare discussed the matter from every standpoint, and showed, by collected opinions of the leading obstetricians in this country, the great diversity of opinion which exists as to the value of quinin as an oxytoxic, and as a stimulant in uterine inertia during labor. The drug was regarded by Dr. Hare as a general stimulant, rather than as one possessing a direct action on the uterus.

Dr. C. P. Noble read a paper on the operation of hysterectomy following previous removal of the uterine appendages, and considered the symptomatology of the menopause after hysterectomy and after salpingo-ophorectomy. He cited six cases on which he had operated, and, along with Dr. Baldy, who discussed the paper, took the ground that the operation was an unsatisfactory one, and that the symptoms which were considered as indications for the operation were due rather to trouble in parts of the body other than the uterus, notably in the arterial supply.

Dr. George M. Boyd reported a case of retention of urine simulating pregnancy. In this case an immense vesical distension caused the woman to imagine herself pregnant; fifteen quarts of urine were withdrawn by catheter during the twenty-four hours after she first consulted Dr. Boyd, with the result that the tumor disappeared, and natural action of the bladder was recovered within the next four days. Dr. John C. Da Costa, in the discussion, recalled similar cases, and cited one in detail, which had been sent to him as a case of ovarian tumor. The use of the catheter removed both tumor and symptoms, nine quarts of urine being withdrawn.

During the past year the death-rate from diphtheria at the Municipal Hospital was 22.2 per cent. Of the 869 cases of diphtheria admitted to this institution during 1896, 553 received the antitoxin treatment in addition to other approved methods of treatment, and of these 142 died, a mortality of 25.67 per cent. Three hundred and sixteen other cases were treated by remedies other than antitoxin, and of these 51 died, a death-rate of 13.29 per cent. At first glance it would appear that this 12.38 per cent. difference in the death-rate demonstrates a decided failure in the serum treatment, but from the statement of the physician in charge of the hospital, Dr. William M. Welch, that a scientific test of antitoxin was not attempted, it may be inferred that the cases not receiving antitoxin were those of a character so mild as not to require it, and, therefore, of a low mortality. On the other hand, assuming that the severer cases received the serum injections, with a death-rate of over 25 per cent. as the result, does it not seem that the antitoxin has failed to materially improve the outlook in dealing with this dangerous malady?

The bacteriologic and chemic investigations which are being made to determine the efficacy of a new system of water purification by electrolysis are exciting interest in medical and sanitary circles. The water to be purified runs through a long wooden trough, in which are suspended three parallel sets of aluminum plates, the positive and negative being arranged alternately. On one side of the trough runs the positive, and on the other side the negative wire from a dynamo, between which the sets of aluminum plates are joined by "multiple connection." The water, flowing between these rows of plates is decomposed by a current of about twenty amperes, the resulting hydrated oxid of aluminum carrying to the bottom of the trough the heavier impurities, while the lighter impurities are floated to the surface by the gases of decomposition. The former are removed from the water by being dumped through a false bottom of the trough, and the latter are carried away by scrapers. A blast of a mixture of ozone and condensed air, forced through the water as it leaves the trough, completes the process. It is said that by this system a plant 100 by 200 feet in extent will "filter" 20,000,000 gallons of water daily, and that the cost of construction would not exceed $75,000. The amount of electrical current necessary for such a plant can easily be furnished at the expense of 50-horse power a day, so that it would appear that the cost of maintenance is inconsiderable.

Out of the total of 920 students in the Medical Department of the University of Pennsylvania, 230 have taken academic degrees, and over 100 additional have pursued for one year or longer collegiate courses prior to their matriculation in the medical school. This proportion of college men is an encouraging sign of the tendency toward a better-educated class of students in our medical colleges, and will undoubtedly increase hand in hand with a higher standard for admission to studies for the doctorate.

Dr. John H. Egan, who for the last five years has been Chief Resident Physician and Registrar of the Medico-Chirurgical Hospital, has tendered his resignation to take effect immediately. This action was taken by Dr. Egan on account of his desire to engage in general practice.

The appointment of the Board of Directors of the Department of Charities and Correction, who control the management of the Philadelphia Hospital, is a matter of real interest to many members of the medical profession in this city, and especially so this year, because of the rumored change in the *personnel* of the Board. The appointment of the directors will be made by the mayor on the fifth of the month, and the names of Drs. J. William White, Conrad Berens, and T. H. Andrews, are prominently mentioned in connection with the places.

The 123d annual commencement of the Medical Department of the University of Pennsylvania will be held on Wednesday, June 9th. The exercises will be conducted in conjunction with those of all the other departments of the university for the first time in ten years.

OUR PARIS LETTER.

[From our Special Correspondent.]

TREATMENT OF CERTAIN NERVOUS DISEASES—OVERCROWDING OF THE MEDICAL PROFESSION IN FRANCE—EXPENSES OF A MEDICAL EDUCATION.

Paris, March 8, 1897.

One hears Flechsig's combined opium and bromid treatment for epilepsy highly commended for cases that have proved recalcitrant to the bromid alone. It is no uncommon thing to see at the Salpêtrière, however, cases that are said to have been treated by bromids, sometimes in large doses, without noticeable improvement, improve rapidly, nevertheless, under a systemized course of the bromids. The system of dosage of the bromids comes from Charcot, who found it extremely satisfactory in the routine treatment of epilepsy, or, as it is often euphemistically called here to avoid wounding the feelings of sensitive patients or their friends, "*mal comitial,*" the comitial disease.

The formula given is:

℞ Sodii bromid.
Ammonii bromid. } aa . . . 23 grams
Potassii bromid.
Aquæ. . . . . . 1000 c.c.

During the first week (in ordinary cases) three teaspoonfuls a day is given; during the second week four teaspoonfuls; during the third week five teaspoonfuls, and then the original dosage is resumed and the course begun over again. When the case is more serious the dosage begins with a higher number of teaspoonfuls, but is increased in the same way. The merit claimed for the treatment is that it gets the patient thoroughly under the influence of the bromids with the administration of the least possible amount of the drugs.

Arsenic does not seem to be combined with the bromids as regularly as with us, but special attention is paid to cutaneous cleanliness and to intestinal antisepsis. Regularly frequent baths and douches are insisted on, something that does not seem unusual over here where the value of hydrotherapy as an adjuvant to other therapeutic measures seems much better realized than in America. As the intestinal antiseptic, benzonaphthol is sometimes used, but salol is much more generally employed, and Marie is even of the opinion that its "crossed action" adds to the direct therapeutic effect of the bromid. Now that urinary hypotoxicity in epilepsy is being more and more acknowledged, and the theory that it is in a certain sense a toxemia is gaining ground, this cross action of salol by its antiseptic effect on the great manufactory of toxins—the intestines—becomes easier to understand.

For the vertigo of Ménière's disease, of which one sees a number of cases, Charcot's empiric use of quinin in large doses is highly commended. It has not succeeded as well outside of France, but here, such great teachers as Raymond, Marie, and Gilles de la Tourette, insist that it *never* fails. The treatment is extremely unpleasant to the patient for a week or two, all the symptoms becoming more pronounced, and he has to keep his bed, but certain improvement is promised. All the same, the use of the salicylates on the same empiric grounds, is suggested and they are sometimes used when the quinin fails.

For chorea, antipyrin is used routinely instead of arsenic, though sometimes the two are combined. One of the nervous specialists said the other day, though not for authoritative publication I think, that it did not make much difference what remedy was used in chorea, that it was always the improvement of the general health that was the signal for the disappearance of the troublesome symptoms, and that no remedy seemed to affect them unless that was secured.

In Europe, almost more than in America, if possible, the serious complaint is being heard that the medical profession is becoming overcrowded. In France this has been the subject of a good deal of writing in the medical journals recently. Paris has now one physician to about every 600 of population, and other places are comparatively no better (or worse) off in this respect. The different universities of France have nearly 10,000 medical students in attendance (Paris alone has nearly 5000 of these) so that the state of affairs promises to grow worse rather than better. The great mass of the French working people, unlike our own, are unable to pay a physician at all, or able to pay him very little, and the dispensaries are crowded with patients. It is not any wonder, then, that the French doctors are in favor of measures that will tend to restrict the number of practitioners. Hence, the recent addition of a year to the time necessary for preparation for the medical degree, and the recent stringent regulations which practically exclude all foreign practitioners and even discourage the attendance of foreigners at French universities unless they expect to practice outside of France. Various suggestions have been offered that might help to deplete somewhat the number of practitioners in France Professor Brouardel, the dean of the medical school, has recently publicly called attention to the fact that there are in Canada 1,500,000 French-speaking people who would prefer to have French-speaking doctors and who cannot always get them easily. Splendid opportunities, it is also pointed out, are open to the French medical men in South America. Frenchmen, however, are deeply attached to the soil, and find it extremely hard to expatriate themselves, so that these suggestions will prove of doubtful utility.

Recently the medical journals have been laying stress upon the expenses connected with obtaining a medical education and the comparatively small returns for the general mass of practitioners in the hope of discouraging parents from allowing their sons to take up the practice of medicine as a life-work. The figures are interesting. It costs from 20,000 to 30,000 francs ($4000 to $6000) for the five years of a medical education, and another 5000 francs are set down as necessary to launch the young practitioner on his medical career. The modern doctor is evidently a high-priced product of our nineteenth century civilization everywhere, but the law of supply and demand holds good for him as for everything else, and the crowding of the profession is fast cheapening his personal value.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

TRAUMATIC NEURASTHENIA—THE DEATH-RATE OF NEPHRECTOMY REDUCED BY THE USE OF THE CYSTOSCOPE—SUBSTITUTION OF THYROID COLLOID FOR THYROID TABLETS—THREE CASES OF RAPID ABSORPTION OF AN ABDOMINAL TUMOR—A PLASTIC OPERATION FOR ULCER OF THE LEG.

HORSLEY read a paper on "Traumatic Neurasthenia" before the Medical Society, February 22. He grouped the cases under four heads according as there was, or there was not, an external injury, and according as the result occurred immediately after the receipt of the injury or at some later period. There is no essential difference between cases of traumatic neurasthenia and ordinary neurasthenia from overwork. Important symptoms are inability to concentrate the attention on any particular subject; disturbances of sleep, especially in the form of early waking; and the occurrence of nightmares or somnambulism. General paresis with twitchings, spasms, and local paralysis usually in the form of hemiplegia of one lower limb sometimes occurs. The tongue is often deviated toward the paralysed side. Smell, taste, and hearing are rarely affected; sight more often so, usually in the form of asthenopia. Various subjective sensations of touch are complained of. Superficial reflexes are at first increased and then abolished, and there is usually ankle clonus. The painful manifestations are usually well localized, especially in certain spots, as, for instance, over the bregma, over the areas served by the posterior branch of the second cervical and the sixth dorsal nerves, the dorsolumbar juncture, etc. Patients often complain of palpitation, particularly at night. The quantity of urine is greatly increased and the percentage of solids diminished.

All of these symptoms are explicable on the supposition that the disease is a disturbance of the central nervous system, and Horsley's experience has convinced him that none of the severe cases recover until they have undergone a course of the Weir Mitchell treatment. Relapses are very likely to occur, even after long intervals of apparent recovery.

CHURTON has seen a number of cases to which formerly the term "miners' neurosis" was applied. The illness was imperfectly understood, and was variously ascribed to ineffective hygiene, syphilis, alcohol, tobacco, etc. It was found, however, that miners often received more or less severe blows on the head or spine, even to the extent of causing unconsciousness, to which they attached so little importance, that they did not think it worth while to mention them to a doctor, but inquiry along this line has shown that there is in almost every instance a distinct history of traumatism. Churton feels that very few of the railroad cases at present met with belong to the class of malingerers, for long after the question of compensation has been settled they sometimes develop myelitis.

FENWICK called attention to *the high death-rate of nephrectomy*, which is largely due to the removal of kidneys which have become affected by tuberculous or malignant disease. One of the chief values of the cystocope is its use in helping us to determine the working capacity of the kidneys. A judicious and skilful use of this instrument not only renders the surgery of the kidney more precise, but also tends to lower the death-rate. No patient with tubercular deposits in the epididymis or the prostate or obvious disease of the bladder should be examined. Carelessly employed, the cystoscope has a death-rate of its own, and it would be better to do exploration on both kidneys than to damage both of these organs by the ascending septic changes brought about by bungling work in the bladder.

All cases of profuse hematuria, either without symptoms or accompanied by slight renal pain, should be judiciously examined with the cystoscope without delay, an operation on the kidney or bladder being permitted and carried out with this cystoscopy. All cases of severe symptomless pyelitis, without implication of the lower urinary or genital tracts, should be judiciously cystoscoped to demonstrate the working capacity of the kidney and to locate the diseased kidney. In women, Kelly's method of catheterization of the ureters is probably a more certain form of exploration. Fenwick has performed nephrectomy after cystoscopy twenty-one times with two deaths, and he attributes this favorable mortality to the use of this instrument.

LOCKWOOD was surprised that Fenwick should declare himself against suprapubic cystotomy with scraping in cases of tubercular ulceration of the bladder, for he has seen several cases in which the operation had afforded great relief. In reply, Fenwick said that small and single ulcers were favorable cases for treatment by suprapubic cystotomy and scraping, and it is difficult to say positively whether these cases are tuberculous. When the tubercular ulceration is extensive scraping can do little good.

At a meeting of the Border Counties' Branch of the British Medical Association, held February 12, PARKER described his experience with *thyroid colloid and thyroid tablets.* He has been especially successful with thyroid treatment in producing the decrease of adipose tissue. In two years he has given over ten thousand thyroid tablets. Recently he has been using tablets made of the colloid constituent in the thyroid gland, and, as a result of these experiments, he has come to the conclusion that a tenth of a grain of colloid is about equal to five grains of thyroid. In some patients he was able, with colloid, to reduce the weight nearly a pound a day without any bad symptoms. He had encountered only one failure. This patient was a woman weighing 173 pounds. She received the same dose he had given to the other patients, and after about three weeks she weighed practically the same as she did before. He had found in cases where patients had taken thyroid extract in undue doses, say about four a day, there was an increase of pulse, and the patient was hot and feverish, sickly, and lost appetite.

At the meeting of the Leeds and West Riding Medical and Chirurgical Society, held February 5th, CHURTON showed *three cases of rapid absorption of tubercular masses in the abdomen.* A boy, aged ten years, with ascites, was given one grain of iodoform in extract of gentian every four hours. Four weeks later the fluid was all gone, but two thick masses remained, one extending from the left costal margin to the umbilicus, and the other in the right lower epigastrium. Four months later there remained only a small area of thickening above and to the right of the umbilicus.

A woman, aged thirty-seven, was admitted to the hospital, with a morning temperature of 98° and an evening temperature of 102° F. Similar treatment was followed out in her case, with the addition of five grains of quinin three times a day. In five weeks the ascites disappeared, and the patient returned home. Six weeks later her abdomen again began to enlarge, and four months after her first admission she was readmitted, and 440 ounces of serous fluid was withdrawn by trocar and canula. A mass the size of two small fists was found in the mid-abdomen. The patient was put upon two grains of iodoform, three grains of extract of gentian, and one ounce of quinin mixture (three grains) three times a day. In two months the mass had entirely disappeared. In a man lately under observation, less favorably placed and less healthy, the absorption of a similar mass occupied nearly a year.

Teale described a case of biliary colic and jaundice, supposed to be due to obstruction of the common duct by a gall stone. Operation was decided upon, but was postponed because the patient was certain some change had taken place in the position of the stone. The next movement contained bile, and a fortnight later, after severe rigor and intense pain, followed by the symptoms of general peritonitis, the patient recovered. Unfortunately, all of the stools were not sifted for gall stones, and none was found. The case is interesting as illustrating the spontaneous recovery after a complete blockage for eight weeks and three days.

Wallis showed a man, at the session of the Clinical Society, held February 26th, who had a large intractable ulcer in front of the shin, the result of traumatism, which had increased in spite of the ordinary treatment. He made two long longitudinal parallel incisions, each, at its center, an inch and a half from the adjacent edge of the ulcer, and having separated the skin from the subjacent tissues, he freshened the edges of the ulcer, and brought them together in the middle line, leaving two gaps representing the lateral incisions, which he filled in by Tiersch grafts. The result, on the whole, had proved very satisfactory, although healing had not yet become entirely complete.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting held December 16, 1896.

The President, **Dr. Henry Ling Taylor**, in the Chair.

J. Blake White, M.D., read an address in memoriam of Dr. Thomas H. Burchard.

A. R. Robinson, M.D., then read the paper of the evening, entitled

THE IMPORTANCE OF EARLY TREATMENT OF CANCER,

which he illustrated with a number of drawings and photographs. (See page 449.)

DISCUSSION.

Dr. William Stevens said that he had been present not long ago at an operation performed by Dr. Abbe, in which he had removed an eye from a woman thirty-three years of age, who had been operated upon five times during as many years for epithelioma of the inner corner of the eye. He asked the author if there was not at times great difficulty in differentiating epithelioma of the lips and mouth from chancre.

Dr. Robert Newman agreed with the author in his opinion that cancer was a local, and not a constitutional disease, although authorities did not agree on this point. The only obstacle to early treatment was the fact that patients did not consult the physician early enough.

Dr. J. H. Fruitnight referred to the fact that the progress of the disease was usually slow unless there was external irritation, in which case it was unwise to defer treatment. He had recently referred three cases to Dr. Robinson, all in the early stage, before ulceration had begun, and the disease had been thoroughly eradicated. The scars were insignificant.

Dr. L. Duncan Bulkley agreed with the author in regard to early and radical treatment. In many cases he had been present when the knife was used, and had insisted upon a large incision and wide removal. He also thought the term "reappearance" better than "recurrence." As the author had pointed out, the fact that an epithelioma might occur after any injury in which changes took place that could take on malignancy, was a valuable one to bear in mind. The speaker said that he did not use the arsenious paste as much as formerly, for he had found that thorough curetting gave better results. For this purpose it was necessary to use a very small curette, so that it might be drilled into the tissues like a gimlet. The procedure was not particularly painful and could be done without an anesthetic, and the scar which resulted was superficial. He had come to the conclusion that cocain was not desirable in these cases, as it made the healing process slower and much less satisfactory. He had also used chlorid of zinc with good results in cases of epithelioma.

Dr. S. H. Dessau recalled a case which illustrated very forcibly what the author had said in regard to the irritation of these growths. A woman had had a small nodule in the breast, accompanied by pain, for a couple of months, which he had advised her to have removed. He did not see her again for two or three months, but in the meantime she had consulted a quack, who had applied a paste to her arm with the idea of drawing the disease out of the breast. The arm was enormously swollen and inflamed. The breast had not gone on to ulceration nor had the nipple retracted. The woman died shortly afterward.

Dr. J. Blake White thought there was no doubt that all cases of cancer should be treated early, but that there were some instances in which the powers of the diagnostician would be pretty severely tested, even with the aid of the microscope, in the early manifestations of this disease. He recalled a case in which specimens were given to two microscopists, and they returned different opinions.

Dr. John F. Erdmann asked the author if cystic tumors had ever been known to take on changes characteristic of scirrhous cancer, and also, what treatment he would advise in inoperable cases?

Dr. W. Gill Wylie said that he had had more experience with cancer in other parts of the body than on the face, and that it was even more difficult to get the cases early, because the disease was not in view and did not attract the patient's attention. In cases of cancer of the uterus, he removed that organ completely with the tubes and ovaries, and, sometimes, with the upper part of the vagina, with very good results. He preferred to do this by the abdominal rather than the vaginal method, because in the former he was better able to determine the extent of the disease. The prognosis in cancer of the vagina was more favorable than in cancer of the uterus, because there was less tendency to lymphatic gland involvement. The cases were usually seen late, because the disease was most apt to appear at the time of the menopause, and the popular belief that "change of life" accounts for every conceivable symptom that occurs is held even by doctors. Then, too, often there was no pain and no hemorrhage in these cases until they were beyond hope. He thought that the "tinkering" which many of these patients receive did much to make the cases hopeless. He had had most excellent results in treating cancer of the uterus by curetting, followed by an application of a saturated solution of chlorid of zinc, protecting the tissues with a solution of bicarbonate of soda. He had never seen a case in which sloughing of the bladder or rectum was caused by it.

DR. J. RIDDLE GOFFE said that with proper attention the early diagnosis of cancer was possible, and, when recognized, the most radical treatment permissable, along the lines laid down in the paper, was demanded.

DR. A. M. JACOBUS recalled the case of a man who for years had had a wart on his neck which was supposed to have been caused by the friction of his collar. Nitrate of silver in the solid stick had been applied, and from that time on the tumor grew rapidly, the glands became involved, and the man ultimately died. The case illustrated the fact that the man might have lived for years had not the growth been stimulated by the nitrate of silver.

DR. R. A. MURRAY said that the author had referred to the knife and arsenious paste as treatment, and asked if he advised nothing else. In the treatment of cancer of the uterus, he thought the best results had been obtained by Dr. Byrne of Brooklyn, by the use of the galvanocautery. In his statistics for the last seven years, Dr. Byrne reported thirty-five per cent. of cures, and in these cases the diagnosis was confirmed by microscopic examination. The cautery destroyed the epitheliomatous tissue by charring, and so mummified it that there was no bleeding. No scarring resulted, and he wondered that it had not been tried in cases of epithelioma of the face.

DR. ROBINSON, in closing the discussion, said that intentionally he had not taken up the subject of different methods of treatment. As the title of the paper indicated, he had dwelt upon the importance of early treatment of cancer, and he had endeavored to show the necessity of this by the etiology and histology of the different types of the disease.

In reply to Dr. Erdmann's question as to whether cysts ever became scirrhous cancer, the speaker said that he had never seen such a case. These tumors were made up of a large amount of new connective tissue cells and plasma cells, and he thought their growth was too rapid to admit of scirrhus changes. He had operated upon what he supposed was a sebaceous cyst on the forehead of a patient, and had found no capsule. Examination under the microscope showed it to be an epithelioma. He removed it with the knife and applied arsenious paste, and, although three years had elapsed, there had been no reappearance of the disease.

In regard to the treatment of inoperable cases, he said that the profession was not in possession of any means that would have any positive curative effect on the so-called "inoperable" cases of cancer, but that there were many things which would prolong life and reduce the size of the tumor. The patients should be made to follow a course of diet and medicine which would cause a change in the nutrition of the part. This would have an inhibitory action on the organism which caused the disease, less toxin would be formed, and growth proliferation, which depended on the influence of the toxins, would be controlled. If no toxins at all were formed, epitheliomata would have no reason for existence.

THE GERMAN MEDICAL SOCIETY OF THE CITY OF NEW YORK.

Stated Meeting held February 1, 1897.

The President, DR. W. FREUDENTHAL, in the Chair.

DR. SIMON BARUCH read a paper on

FAULTY HYDROTHERAPY,

Which he opened with the statement that, despite its antiquity, water has not yet obtained a firm footing in therapeutics; despite its marked clinical results, it still requires to be brought to the attention of practitioners; despite its espousal by the best authorities in ancient and modern medical practice and literature, the average medical man is not familiar with its history, action, and merits. Dr. Baruch regarded as the chief reason for this state of affairs the absence of instruction in hydrotherapy in the curriculum of medical schools, to which is due the ignorance of the rationalé of the action of water and the unfamiliarity with its correct application, which are found among the majority of medical men. The consequent indifference to definite methods has rendered its application in the hands of many unsuccessful and discouraging. Failure is the sure result of inattention to details. As the physician must judge the value of a remedy by his experience, it followed that failure to achieve the results which the experience of others had led him to expect has brought this remedy into disrepute, the fact unhappily remaining unrecognized that not the remedy, but its improper application was at fault.

Although water is a simple remedy and appears to be so easily applied, no remedy in the entire materia medica demands a like judgment and care in its application. As an illustration an incident was referred to, showing how a brilliant young hospital physician shrank from the Brand bath in typhoid fever, because he had seen a patient die under cold-water treatment, which consisted in wrapping the patient in a sheet and sprinkling her with ice water. The object of the Brand bath is to sustain the nerve-centers first and to reduce the temperature secondarily. Although the latter was regarded as an index of gravity in most cases, the bath was not intended to combat it. A bath of 65° F., with friction for twenty minutes every three hours, whenever the body temperature reached 102.5° F., is calculated to arouse the nerve-centers from their lethargy and give an impetus to all the dormant functions depending upon them. The low temperature of the bath irritates the peripheral sensory filaments, from which the irritation is conveyed to the central nervous system, to be reflected upon the heart, lungs, and secreting organs. Friction adds to the irritation by multiplying it, the cold water being kept in motion; cold affusion over head and shoulders is added to promote the same object. *To whip up the nervous system* (as is done in cases of poisoning by narcotics) is the object of the Brand bath. But day by day, with occasional disappointments, a fifth, or a quarter, or a half degree of temperature is gained; the heart maintains its vigor, the kidneys increase their work, the stomach receives more kindly the proffered nourishment; sleep is won.

By this method the enemy cannot be routed, the disease cannot be shortened, but we hold his ravages in check surely and completely until his reinforcements fail. The bacterial life period reaches its end, the toxins cease to be evolved, and at last the physician stands conqueror of this deadly enemy. This is the true aim, the correct rationalé of the Brand bath. Were temperature reduction the chief need, we would have the key to the situation in our splendid coal-tar antipyretics; were pulse reduction the desideratum, veratrum viride would prove an open sesame; were nourishment the chief object, there is no lack of this in modern culinary and chemical art. But all these are as naught in the face of a toxemia which overwhelms the nerve-centers of the most robust as well as the most feeble patients. To wrap the patient in a sheet and then sprinkle him with ice-water, as was done in the case cited, is a deviation from the correct technic of the typhoid fever bath. Such a procedure does not fulfill the main object of arousing the nervous system. After the first shock has passed, no opportunity is given for reaction, because the sprinkling of ice-water continues, the cutaneous vessels and elastic tissue of the true skin contract, as evidenced by cutis anserina; the extreme cold imparted by the wet sheet, without remission, benumbs the sensory nerves and thus impedes the transmission of the shock and subsequent stimulus, even if the latter has ensued in an exceptionally strong individual. This faulty technic frustrates completely the true aim of the cold bath. The surface temperature is, indeed, reduced by this improper method, but the blood is driven to the interior, congestions are favored, the organs are overloaded, and the patient emerges from such a bath (save the mark!), a shivering, cyanosed weakling. The ideal results obtained by Brand and others in 1200 cases, without mortality, can only be realized by following the exact technic of Brand.

Dr. Baruch claimed that physicians have failed to obtain ideal results, because they deviated from the ideal technic, each one modifying it to suit his own fancy. He insisted that to the free deviation from its correct technic may be ascribed the lack of appreciation of the therapeutic value of the Brand method. Those physicians who have mastered its technic will agree with Prof. Delafield, who teaches that immersion in cold water is the only real treatment of typhoid fever, and the only way to practice this treatment is the exact method of Brand. In the treatment of all diseases our teachers insist upon correct dosage of medicinal agents, the exact time and mode of their administration, frequency of repetition, and even their exact preparation. Similar care and attention should be given to the prescription of water as a remedy.

In chronic diseases a correct application of water is quite as important as in the acute. A prescription for a bath or other hydropathic procedure, without exact statement of temperature, duration, pressure, and method, is as absurd as a prescription for a medicine without stating dose and method of administering. The import of pressure, temperature, and duration of every hydropathic procedure requires to be impressed with emphasis. Every physician realizes the difference of effect arising from different temperatures, and yet we commonly read directions for cold, hot, or tepid baths. By gradually accustoming tuberculous patients to lower temperatures and stronger pressure, very favorable results have been obtained in private and hospital practice. If low temperatures are used at once the patient is shocked and depreciated. The same may be said of neurasthenic and other chronic cases, in which Dr. Draper was cited as claiming that "the results of hydrotherapy are striking, but more effective than medicine."

The author especially inveighed against the gradually cooled bath, which is intended to avoid shock and be pleasant to the patient. Such a bath does not fulfill its object properly, because the surface vessels are relaxed by the warm water; reactive capacity is diminished by its calming and sedative effect. The vaso-constrictors are depressed. The subsequent cooling of the water finds the sensory nerves unprepared, and chilliness usually results unless the patient be more robust than is the average neurasthenic. It is unhappily a very prevalent error to regard the most agreeable bath as the most salutary. We do not so reason in the application of medicinal agents, of electricity, or diet. And the application of water may be made agreeable by gradually accustoming the patient to lower temperatures, slowly reducing them every day or two, making the application brief at first, and increasing the duration and pressure day by day. The prime essential, however, should always be borne in mind, that reaction is our aim, that this cannot be evoked without some shock, that the more intense the latter the more effective the reaction, but the more brief it is, the less unpleasant. If the physician bear in mind that his object in treating such a case is an increase of the quantity of blood circulating in the cutaneous vessels, an enhancement of the nutrition, a stimulus to the entire nervous system, he will endeavor to so order the technic, provided he has mastered its details, so that day by day the reactive capacity may be elevated. As the shock and reaction increases day by day, the patient will emerge from the treatment with a ruddy hue. The increased circulation will endure more and more every day, languor and loss of appetite will cease, and if the patient does not fully recover under this domestic treatment, douches of the same temperature and with a pressure of twenty-five to thirty pounds, preceded or not by hot-air baths, will bring about a final restoration of health.

In acute cases like typhoid fever, which are under constant observation of the physician, the latter may at once note the result of an improper use of water and modify it, or, as is more often the case, relinquish it altogether. But in chronic cases much damage may be done before the physician discovers it, if the treatment be not in the hands of trained and intelligent attendants who are under medical supervision. Too often the details are left to nurses, because physicians have not received instruction in the rationalé and technic.

Dr. Baruch concluded by saying:

First. That the therapeutic application of water demands at least as much care as the use of medicinal agents.

Second. That, owing to the flexibility of water as a remedial agent, greater demands are made upon the practitioner than in the use of medicines.

Third. That the best results may be obtained only by following an exact technic in each case.

Fourth. That the reason that different results are obtained by different physicians from the application of water may be found in the technical errors committed on account of an erroneous conception of the rationalé of hydrotherapy.

DISCUSSION.

DR. I. ADLER said that in the most modern medical view hydrotherapy plays an important rôle, and that, as Dr. Baruch had emphasized, the application of water is so lax that, clinically and diagnostically, much less is accomplished than would otherwise be. But this is not alone the fault of physicians, but, perhaps, as much of those who specially cultivate hydrotherapy. The latter seems to be based more on personal impressions than scientific data. We cannot accept water, therefore, on the same basis as our medicinal agents. As an example, the physiologic action of strychnin upon the spinal cord is exactly known, but of water we cannot say this. There should be a knowledge of the physiologic action of water ere we are asked to accept it as a scientific remedy.

Dr. Adler thought it is going too far to accept the baths as the only remedy in typhoid. To him the statistics cited by Dr. Baruch, to prove that the mortality has been reduced to almost nothing, are new. He had used the baths more in hospitals than in private practice, where the treatment is more difficult to apply. One may have very good results without baths, although the latter are one of our very best agents where the heart is feeble, delirium is intense, and somnolence occurs. He could not accept Brand's rule, supported by Dr. Baruch, that 102° F. should be the signal for baths. Some patients become delirious at 100.5°; others may have a temperature 105° F. and not be delirious. He also expressed confidence in small doses of antipyretics, which afford much relief, although he did not approve of their routine application for temperature reduction.

DR. L. WEBER had always used cold baths in typhoid in the absence of kidney complications. He begins the treatment with a large dose of calomel to clean the intestinal tract and disinfect it. In private practice he had not often had an opportunity of applying the Brand method. There seems to be a silent but active opposition to it among the nurses. There is no doubt that Brand's method offers great advantages, and is specially adapted for enhancing the resisting capacity of the nervous system. He used antipyretics in small doses for temperature reduction. In neurasthenia he had seen much of hydrotherapy. It seemed to him, however, that many of these cases recover under any treatment.

DR. A. ROSE opposed Dr. Adler's views that hydrotherapy was not based upon sufficient scientific investigations and experiments. It would seem that the statements of quacks are more regarded than these scientific experiments. He referred to the plethysmograph of Winternitz, by which the passage of blood, driven from one part of the body by cold baths, was demonstrated in other parts. Dr. Rose referred to his experience in erysipelas, and his observations with the permanent baths in obstinate rheumatism.

DR. A. SEIBERT believed that the complaints made by hydrotherapists, that their doctrines have not been generally accepted by the medical profession, are to be charged to their own writings, in which they use many hyperboles. The Brand bath is not responsible for the reduction of mortality of typhoid fever during the past thirty years; it is due to the general improvement in the treatment of the disease. A large acquaintance with statistics enabled him to say that many sins are committed with statistics. In his hospital practice he uses the Brand method only on patients who are received in a somnolent condition. He prefers to reach the seat of the disease by cleaning and bathing the intestinal tract rather than to cool the skin and then excite the nervous system. He regards as novel the claim that the early adoption of the Brand method is capable of affording absolute protection against complications.

DR. TALMEY believed that one reason for the nonacceptance of hydrotherapy lies in the objections of the public; another reason lies in the insistence of the hydrotherapist upon so many details, which no ordinary man is presumably as capable of executing as they.

DR. BARUCH closed the discussion by insisting that the proof exists showing that the action of water is more rational and scientific than that of any other remedy. Very little is known of the action of strychnin in non-toxic doses. It may be administered for days, weeks, and months without any subjective or objective evidence of its presence, in the pulse, blood pressure, respiration, etc. Of water we know much more. It may be dosed with precision afforded by a latitude of seventy degrees of temperature (35 to 110), a duration of a second to many minutes, a pressure of from one to forty pounds. We also have various methods of applying it (by packs, baths, douches, etc.), by which its effects may be graded. A few days ago he subjected an attendant in the Hydriatric Institute to a tub bath of 80° F., for ten minutes. The effect was at once pronounced upon the pulse, as ascertained by the finger and the sphygmograph; the blood count showed an increase of 700,000 red cells and 1500 white cells in blood drawn from the lobe of the left ear. Is any analogous experiment with non-toxic doses of strychnin on record? So far from there being a lack of scientific experiment regarding the action of water, many have been made within the past five years, in Zunt's and other laboratories by Breitenstein, Loewy, Knoepfelmacher, and others. Thayer, of Johns Hopkins Hospital, has confirmed the statements of Winternitz and Rovighi, that the red and white blood-cells increase after cold-water applications; the sphygmomanometer has demonstrated that the force of the heart is increased by them; Vinaj has shown with exactness by the ergograph of Mosso how the muscular power is enhanced by them; Roque and Weil have shown that the urotoxic coefficient of the urine in typhoid fever is manifoldly increased after the use of the cold bath.

That early cold baths prevent complications has been demonstrated as no fact in medicine has been demonstrated before. Dr. A. Vogl, Medical Director of the Bavarian Army, has collected from the records of the Military Hospital of Munich all the cases of typhoid fever which were treated during a period of forty years in this hospital. He gives the type of the disease each year, the symptoms, the treatment, mortality, and results of autopsy. Since the strict bath treatment was adopted he found the mortality reduced to 2.7 per cent., while under other methods of treatment it had ranged from fifteen to thirty per cent. This proves that the result is not due to a change of type in the disease, which the records show to have varied from year to year during this long period, but that it is entirely the result of the bath treatment which prevented lethal complications. Although the Brand method must be applied before the fifth day, every fever patient may be bathed with advantage. Dr. Baruch stated that he invariably uses it in private practice; that he declines to treat the patient otherwise, and that he has been dismissed from a case but once for this reason.

Contrary to Dr. Talmey's naïve accusation, modern hydrotherapists have taken pains to simplify hydrotherapy and make it the common property of physicians. But this cannot be accomplished so long as the latter persist in their skeptical attitude. The most superficial study will demonstrate that water produces a thermic and mechanical excitation of the cutaneous nerve endings which operate upon motor and sensory tracts as a reflex upon the circulation, respiration, and secretions. These demonstrations are so abundant in literature that he would regard it as an insult to the intelligence of his audience to reiterate them.

That a woman may be aroused from syncope by the simple sprinkling of cold water upon the face, is known to almost every lay person, and the scientific explanation of this process is recognized by every tyro in medicine to be a powerful irritation by cold, which is conveyed from the cutaneous nerves to the central nervous system, and thence by reflex to the vagus. This seems, perhaps, too simple. Rabbits and guinea pigs are not required for the "scientific" explanation of this powerful effect. If such sacrifices are demanded, however, to establish water as a scientific remedy, the classical experiment of Maximilian Schüller upon trephined rabbits may be offered. Schüller exposed the vessels of the pia, and placing the rabbits in water at different temperatures, observed the effects of these applications on the animals. He demonstrated more clearly than has ever been done in the study of any medicinal agent the effect of these water applications. He showed conclusively that the latter called into action a hydrostatic effect, which makes water a powerful agent for influencing the circulation of blood in an animal. Besides, Winternitz and others have demonstrated in the most exact manner, by laboratory experiments, that the corpuscular elements of the blood are subjected to such decided changes by water applications that no medicinal agent is capable of approaching their effects.

To Dr. Talmey's insinuation that hydrotherapeutists are so insistent upon details that it is difficult for an ordinary mortal to follow their directions, Dr. Baruch replied by protesting against the tendency of physicians to leave the water treatment of chronic cases to bath attendants, or other nurses who claim to know all about it, but really do not know anything but the mechanical part. Does not every physician who orders a cold bath in typhoid fever give the nurse directions regarding temperature, friction, drying, duration, etc.? Why, then, should physicians leave such important details to a nurse when ordering a wet pack, douche, etc., for a chronic case? Would it not be far easier for physicians to consult some work on this subject and use their own judgment in ordering the necessary temperature, duration, etc.? It is just as absurd to leave these important details to self-important bath nurses as it is to leave the doses of a medicine to the druggist to prescribe and administer. Indeed, the latter would be safer, because the druggist is, at least, an educated man. As Vogl has said, leaving the treatment entirely in the hands of lay people has brought hydrotherapy into disrepute.

That the hydrotherapists "resort to many hyperboles in their writings and lectures" may, as Dr. Seibert states, be true. But the most eminent physicians also resort to "hyperboles" when they have mastered hydrotherapy and applied it correctly.

Dr. Baruch said that he might quote many "hyperboles" from the writings and lectures of the most eminent clinical teachers. These gentlemen have not been deterred by the "hyperboles of the hydrotherapists." They have investigated the subject, as have Delafield, Peabody, Osler, and Draper in our own country, and have become consistent advocates.

One thing Dr. Baruch desired especially to emphasize, namely, that in his article, as in all his writings, he has never lauded water as a universal remedy. He claimed that his observations in hydrotherapy were gathered in the capacity of family and hospital physician, in which respect he stands alone. As a practitioner of thirty-five years' standing, he did not feel prepared to throw aside calomel, salicylic acid, morphin, quinin, and other approved remedies. Despite this fact he felt compelled to acknowledge that water has served him well in the most desperate chronic cases after other most approved remedies had failed in his own hands as well as in the hands of colleagues. For this reason he would say with Pindar, *αριστον με̋ ν ὕδωρ*. And herein he felt himself sustained by the most eminent clinicians of the present time, whose opinions he desired to impress upon his colleagues.

REVIEWS.

A Handbook of Pathological Anatomy and Histology, with an Introductory Section on Post-Mortem Examination and the Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., and T. M. Prudden, M.D. Fifth edition. Illustrated by 365 wood engravings; printed in black and colors. New York: Wm. Wood & Co.

In the preface to the fifth edition of their work, the authors reiterate the statement that it has been their intention to give to students and practitioners of medicine the knowledge necessary for the making of autopsies, the preservation of tissues, and their preparation for microscopic study, and to outline the methods of study of pathogenic micro-organisms; and, to describe concisely, with such illustrations as seem necessary, the lesions of the active infectious diseases, and, so far as they are known, the microorganisms concerned in their causation, the various phases of degeneration and inflammation, the character of tumors, the special lesions of different parts of the body, of the general diseases, of poisoning, and of violent death. The general plan and make-up of the book has not been changed in this last edition, and what has been said in praise of it heretofore might be said again, for more than ever does it deserve such laudation.

The section on *post-mortem* examination is, considering the small space allotted to it, very satisfactory; that devoted to general methods of preserving pathological specimens and preparing them for study is less so. When we say that no mention is made of a method of staining that is probably used by every pathologist to-day, namely, that of Mallory, we shall have made our reasons for this statement clear. The section on the blood has been rewritten by Dr. James Ewing, and it is a fairly accurate reflection of the views of those who have made their names familiar to all students of blood pathology. A beautifully executed plate lends color and value to this chapter. The chapters on inflammation have been subjected to revision, but to no very great change. That on animal parasites is practically unchanged, and we miss mention, either by word or picture, of the *anchylostoma duodenale*, which for a time it was believed, was found only in certain parts of Europe and the Orient, but which it is now absolutely certain occurs in this country. The chapter on vegetable parasites is a most commendable one.

The authors frequently adopt an attitude of reserve toward many questions on which other equally gifted pathologists are frequently dogmatic. We may cite, for instance, the statement that "it seems probable from what we know at present that several forms of bacteria are capable of causing acute cerebrospinal meningitis." To us, if we understand that reference is made to the epidemic form, this seems highly improbable, and the more carefully the evidence at hand is subjected to critical examination the more does it appear that the *diplococcus intracellularis meningitidis* is the real cause of the disease when it prevails epidemically.

The section devoted to the diseases of the nervous system is the least satisfactory one in the book. Many diseases on which the student and the practitioner need very much light, such as the primary systemic diseases of the spinal cord, simple and combined, are not mentioned, and we are very doubtful that it is of the least service to endeavor to convey to the student's mind the essential pathological features of amyotrophic lateral sclerosis by saying that "degenerative changes of both the central motor neurons from the brain to the cord, and of the peripheral motor neurons from the motor cells of the cord to the muscles, may be diseased, and these conditions determine a replacement fibrous hyperplasia in the lateral column, and also in the anterior cornua of the spinal cord." This condition has been called "amyotrophic lateral sclerosis," even though this be accompanied by a picture. Quite as much as this may be obtained from the study of any good dictionary. Such important subjects as progressive spinal muscular atrophy and bulbar paralysis, are given three lines, while malformations of the cord are given as many pages. We are glad to turn from the nervous system to the respiratory and vascular systems. Here the authors write with a clearness and certainty that comes from long familiarity with the subject and from positive convictions.

The reputation which previous editions of this work made for its authors will be enhanced by the present one. The mechanical part of the volume is very satisfactory.

Atlas und Grundrics der Verhandlehre. Von Dr. Albert Haffa, Privatdocent für Chirurgie an der Universität Würzburg. München: J. Lehman, 1897.

The author of this handbook of bandaging is well known as an orthopedic writer of prominence. The text of this work does not differ much from similar works, except in its completeness and in the beauty of its illustrations. These are all copies of photographs and enhance the value of the book immensely, while they elucidate the text much better than photographs usually do. As a thorough exposition of the art of bandaging, the book may be heartily recommended.

Report of the Commissioner of Education for the Year 1894–95. Vol. i, part i. Washington: Government Printing Office, 1896.

This report contains a large amount of statistical and other information concerning primary and higher education in the United States and Europe, with a special report on the higher education of women, and on the Chautauqua Assembly. The student of pedagogy will find in this volume a fund of information.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, APRIL 17, 1897. NO. 16.

ORIGINAL ARTICLES.

ECTOPIC GESTATION.[1]

BY H. J. BOLDT, M.D.,
OF NEW YORK;
PROFESSOR OF GYNECOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; GYNECOLOGIST TO ST. MARK'S HOSPITAL AND TO THE GERMAN POLIKLINIK; CONSULTING GYNECOLOGIST TO BETH ISRAEL HOSPITAL, ETC.

AFTER putting the outline of an intended paper on ectopic gestation together, I began to look over the literature on the subject, and then came to the conclusion that, after the many masterly contributions which have already appeared, I could not add any valuable new material. Therefore, I shall take up your time only with the conclusions which I have derived from my personal experience, in a series of nearly one hundred cases of ectopic gestation, seen in my practice.

The causes of ectopic gestation are by no means definitely settled. Undoubtedly, in a great majority of instances, some form of inflammatory disease of the pelvic organs acts as a predisposing factor. I have formerly asserted that in every instance a tubal inflammation is present, usually a catarrhal salpingitis; but during the past few years I have met with several cases in which nothing of an inflammatory nature could be attributed as the cause, and, consequently, I have been compelled to accept the view, put forth by experimental investigation, that, in some instances at least, the etiological factor is that the spermatozoa pass directly into the Fallopian tube, and then meet the ova, and an imbedding takes place, though the tube be in normal condition. If the Fallopian tube be inflamed, even though to a slight degree, or if distorted, as the result of inflammation, or if there is a neoplasm in it, it is readily conceivable that the impregnated ovum remains in the tube; yet, as said before, I feel convinced that there are exceptional instances in which no such pathologic condition exists; therefore my acceptance of the theory mentioned.

The internal migration theory does not seem plausible to me, because the immediate increase in size of the ovum, when it comes in contact with the spermatozoa in the uterine cavity, would seem to me to make it highly improbable that the product should migrate back into the tubal canal. The attachment may take place in any part between the ovary and the uterus, or in either of these organs.

For the diagnosis of an ovarian pregnancy it is necessary that the respective Fallopian tube be intact and in normal condition, except for its increase in size and the circulatory changes necessarily accompanying such enlargement. The gestation sac must be amidst normal ovarian tissue, and distinctly separate from the tube. Of this variety I have not seen any case, although they do exist beyond doubt.

The variety called intramural by Hennig is probably the next in rarity. It is a slight variation of the interstitial variety in degree only, the interstitial being that form developed in the uterine portion of the tube. In the intramural form, the conception product buries itself in the adjoining muscular structure of the uterus.

I have seen one instance of this variety. On December 13, 1883, I was called to see Lena D., twenty-two years old, who had been married about three years, and presumed herself pregnant for the first time, it having been more than two months since her last menstruation, and, besides, she had had several other symptoms of pregnancy, such as morning sickness and shooting pains through the breast. While dressing her hair she was attacked with an intense, sudden pain in the lower abdomen, so severe as to cause her to fall. This was followed by collapse. The pains continued severe, with slight intermissions, for several hours. Death occurred on December 17th, from peritonitis. On autopsy, the rupture was found to have taken place on the posterior surface of the corpus uteri, near the tubal junction. The abdomen was filled with blood of about the date corresponding to the first day of the attack, showing that had an operation been performed after the subsidence of the collapse, the patient, perhaps, would have been saved.

That a true, primarily abdominal pregnancy exists, is doubtful to many, and I confess to belong to the latter class, believing that primarily the gestation is of the tubal or tubo-abdominal variety. The nearest approach to what may be called abdominal pregnancy in my experience is illustrated by the following case, which was classified under that heading and published in the *American Journal of Obstetrics* in 1880 by the late Professor Montrose A. Pallen:

> In November, 1879, I saw a woman, twenty-three years old, the mother of two children, the last being born in August, 1875. At the time of my call on her, which was for the purpose of attending her in confinement, she presumed herself to be then in labor. She gave a history

---

[1] Read before the Obstetrical Section of the New York Academy of Medicine, February 25, 1897.

of having suffered from inguinal pains for three months, but for the past two days to these pains had been added intense labor-like pains, of such severity that she expected to be delivered at any moment, although she considered herself but six months pregnant. The examination showed what seemed to be the vertex tightly wedged in the cul-de-sac of Douglas, with the vaginal portion of the cervix crowded up behind the symphysis. In the hypogastrium a round, smooth, and elastic tumor was felt, which was considered to be the breech. My attempts to correct the supposed malposition being useless, I called in several gentlemen in consultation, and all agreed with me as to the continuance of the treatment pursued, and also in the diagnosis. I presumed that I was dealing with a gravid retroflexed uterus, and endeavored to correct the malposition.

Professor Pallen operated with the intention of doing a Cæsarean section, when it was found that the condition was an abdominal gestation. The position of the child was as diagnosed previously. The sac containing the fetus was apparently independent of the tubes or broad ligaments, yet no *post-mortem* being obtained (death of the patient having taken place on the morning following the operation) we are not in a position to say anything positive as to the primary seat of the gestation, and whether it was tubo-abdominal and later developing into true abdominal or otherwise. Dr. Pallen, at the time when he reported the case, stated that he extracted a dead fetus. This statement should be corrected, for the fetus lived several minutes after extraction.

The most common variety of ectopic gestation is the tubal, which may of course occur in any section of the canal. In one instance I have operated twice on the same patient for tubal pregnancy, with an intermission of five months. The first time the left tube, and next the right, was the seat of trouble.

Termination.—It is but seldom that ectopic gestation will go on to full term. Usually it is interrupted between the second and eighth week; more frequently before the tenth week than later; but by no means is it the case, as supposed by some, that a rupture of the tube is a necessary termination. In my own experience tubal abortion is nearly as frequent. In some instances death of the embryo occurs and the products of conception become innocuous and are absorbed. Again, it may occur in interstitial or tubo-uterine pregnancy; that it is changed into true uterine pregnancy the following example, which I add to those already known, bears out this statement, which is so strongly opposed by Mr. Tait:

February 18, 1886, Mrs. M., thirty-three years old, married eleven years, four children, all normal deliveries. Two and one-half years had elapsed since the last confinement. Since the 3d of the month she had suffered with pain in the right hypogastrium, which radiated over the entire abdomen and down the right thigh. The pain was nearly constant, and was described as being cramp-like in character. The uterus was somewhat diminished in consistency, and slightly enlarged. On the right side it was considerably thickened and painful on bimanual examination. The enlargement was distinctly felt to pass a trifle outside of the uterine boundary into the tube. On February 22d a sound was passed into the uterus which was found to be empty. On that day a faradic current was used as strong as the patient could comfortably bear it, the positive pole being placed over the tubo-uterine tumor with the intention of destroying the vitality of the ovum, inasmuch as I had determined satisfactorily to myself that we were dealing with a tubo-uterine pregnancy. I find four such treatments recorded in my notes. At the time of the intended fifth treatment all the pains had disappeared and with it the enlargement of the right side of the uterus and tube. The patient was eventually delivered of a living child at full term by myself.

This case seems to me to be quite conclusive of the possibility of a termination such as that mentioned above.

An ectopic gestation may advance to full term and a living child may be obtained, but such is indeed a rare exception, and one that we have no right to expect. In other cases the fluid contents are absorbed and a lithopedion results, as in the case demonstrated at the meeting of the American Gynecological Society by Dr. Lusk. I have in my practice seen only one instance in which the pregnancy had gone to full term, and in this case suppuration of the sac and maceration of the fetus ensued, so that the patient was septic at the time of operation. In some such cases the sac may rupture into the bowel or bladder and recovery finally take place after a serious and long illness, the contents gradually being expelled through the rupture. Of such a termination I have also seen one instance.

Rupture may occur into the folds of the broad ligament, and with cessation of the bleeding, the products of conception with the extravasated blood may be absorbed; or, in some cases, we may have the formation of a retro-uterine hematocele, if the bleeding process is slow and pelvic inflammation is present, which aids in the encapsulating of the blood, and this, too, may then be absorbed. Such a process I believe is more apt to be present in cases of tubal abortion when the fimbriated extremity of the tube is attached to the pelvic floor.

Diagnosis.—Before the beginning of an abortion or rupture I consider the diagnosis to be a very difficult matter in the early stages, unless there has been an opportunity to make a number of observations of the case, because it is seldom that patients consult us until the onset of the symptoms. One reason why the specialist so seldom has the opportunity to see cases of unruptured or unaborted tubal gestation is that the patients seldom have much cause for complaint before the beginning of the usual termination and so do not think it necessary to consult a physician, but if they do consult the family physician, he usually does not recognize the condition as being sufficiently serious to call a specialist in consultation. It is, therefore, of the utmost importance that the general practitioner should be sufficiently acquainted with these abnormal conditions and that he be on the alert so that he may be able to make the diagnosis. After the beginning of such a catastrophe the diagnosis should not be difficult. I have but one instance to record in which the diagnosis was not made, and since then an opportunity has been afforded me sixty-two times to operate for ectopic gestation, in which it was corroborated in each instance. *The sixty-two cases resulted in fifty-eight recoveries and four deaths.* The characteristic features are the cessation of the normal menstrual period for a greater or lesser period of time (usually from a few days to five or six weeks); the occurrence of intermittent cramp-like pains in the lower abdomen, notably beginning on the affected side and then radiating over the entire lower abdomen; a discharge of thick, dirty chocolate-colored sanguineous fluid, in variable amounts, which adheres to the examining finger (the irregular bleeding usually is indicative of the death of the embryo); the uterus enlarged and of the consistency of a uterus affected with chronic hyperplasia; to the side of the uterus a mass, intimately adherent to the organ, in many instances traceable into the retro-uterine space. The mass has no definite outline, varies in size, and is of a hard consistency, but not as firm as ordinary inflammatory exudate, feeling somewhat similar to a pyosalpinx surrounded by perimetritic products. In nearly all cases the breasts contain colostrum. The discharge of a decidua adds to the certainty of the diagnosis, but I must confess that despite the stress placed by most writers on this last objective symptom, I have found it absent in many of my cases, so that I do not place very much significance upon its absence. The blood later on changes to a bright red in spots, in some instances, and in others again, it assumes the bright red color after three or four days' time. The presence of anemia, more or less marked, is prominent in all cases according to the amount of blood effused into the peritoneal cavity.

I have not been able from my experience to lay down any rules enabling one to differentiate tubal abortion from tubal rupture. Those which have been placed before the profession do not bear out my experience.

From these characteristic symptoms many variations occur under different circumstances. I have, for instance, seen one case in consultation in which the only symptom, in addition to the hyperplastic condition of the uterus, was the sudden occurrence of extreme weakness and marked anemia. Upon these two conditions the probable diagnosis was principally based. There was a suspicious feeling in the cul-de-sac of Douglas as though free fluid were present, but it was by no means prominent enough to enable one to say with certainty that such was the case. It was found upon abdominal section that the right Fallopian tube, which was the seat of an extensive rupture, was held high up in the pelvis by old inflammatory bands.

In the later stages of pregnancy the diagnosis becomes much easier. Here the size of the tumor, its gradual growth, and other more marked symptoms of pregnancy all aid one to make a correct diagnosis. I have purposely refrained from speaking of pregnancy in a bicornate uterus, because I have had no personal experience with the condition.

Treatment.—I believe that the advocates of electrical treatment in such cases are rapidly diminishing in number. We should consider an ectopic gestation in the same light as a malignant neoplasm. There is no doubt in my mind that electricity, especially the galvanic current, has been used with advantage, as one can see from the careful treatise on this subject by A. Brothers in the *American Journal of Obstetrics*, yet at the same time it is in my opinion more dangerous than is operative interference in the hands of an experienced surgeon. The death of the embryo does not preclude either the danger of hemorrhage or the danger of decomposition of the sac contents. As to the injection of narcotics into the sac, as practised by Von Winckel and some others, the danger is the same as far as suppuration is concerned, yet in a locality where it is impossible to procure an experienced operator either one of these methods is safer for the patient than operation, and should be advised.

In early ectopic pregnancy the operative plan is understood by all, and I do not think any one is at variance as to technic if the abdominal route is chosen.

One error frequently committed is that the patient on account of unfavorable surroundings is transported to a hospital for operation when she is suffering from a ruptured tubal gestation. This is a very serious mistake, as such patients often do not bear the removal, or during the transport have another and perhaps fatal intraperitoneal hemorrhage. Hence, I have usually considered it wisest to operate upon such a patient at her own home, despite bad surroundings, because the surgical work can be done just as aseptically and thorough, although the inconvenience to the operator is tenfold. The after-treatment under these circumstances is surrounded by numerous and serious difficulties, especially if a drainage tube is left in the abdomen. This objection does not hold good with me, because I do not use a drainage tube. If the adhesions are so numerous that they cause considerable bleeding when separated, an intraperitoneal gauze packing is employed according to the method of Miculicz, and the subsequent absorbent-cotton dressing on the abdomen is sufficient to protect the wound under all circumstances. As to the other after-treatment, it can be carried out satisfactorily, so far as my experience goes in probably more than 300 abdominal sections performed under these so-called unfavorable surroundings. My idea is to stop the bleeding in such a patient wherever the patient may be.

Again, I have not found it necessary to wash out the abdomen and to remove all of the blood in the careful manner usually advised. Formerly I practised this, but latterly have not, and I have come to the conclusion that on account of the blood being rapidly absorbed by the peritoneum, it is more to the interest of the patient to shorten the operation, than to lose twenty minutes or more upon an exceedingly careful toilet of the peritoneal cavity. This, of course, only holds good for such cases as those we have under consideration.

I do not care to operate when the patient is in a condition of extreme shock, or better say, collapse, because under such circumstances the patients do not bear an operation of such magnitude well, and usually it is possible to rally them to a better condition when there is at least a fair heart action, if the cases are properly treated. As soon as this has been achieved no time should be lost and false hopes entertained, but the operation should be performed as rapidly as possible, for, with the extremities bandaged and with proper stimulation, everything for the operation being in readiness, the bleeding tube can soon be tied off, with a favorable chance of recovery of the patient.

In unruptured ectopic, or if rupture has taken place and the uterus is freely movable, I consider that the vaginal operation should have the preference. To Dührssen belongs the credit of having first performed and published it, but without the knowledge of his work and before his publication, I also performed vaginal celiotomy for ectopic gestation and presented the specimen before the New York Obstetrical Society. I would not, however, recommend that the operation be performed from below indiscriminately.

In advanced ectopic gestation, it was formerly customary to leave the placenta *in situ* and to sew the sac wall to the abdominal wall, packing with gauze and irrigating the cavity. This is a method which should not be used unless the adhesions are so dense that it is absolutely impossible to separate them. If possible, the entire sac should be enucleated. If suppuration has taken place, however, the old procedure is safest.

The form of treatment of pelvic hematocele due to ruptured extra-uterine pregnancy has two sets of advocates. I was surprised, when a paper was announced on a "new treatment" for this condition, to find that it was one which I thought was practised by everyone, but I was still more surprised when, in the discussion which followed its reading, there was a variance of opinion as to the treatment of the condition from below or above. It, therefore, seems evident that no unanimity of opinion exists, so far as the treatment is concerned. In some cases the blood will gradually become absorbed; in other cases, however, the pressure effects are so great that something must be done; and, again, in other cases, suppuration necessitates interference. If the exudate is small, and does not give rise to any alarming symptoms, it is sufficient to command absolute rest and apply an ice-bag over the abdomen; if some pain is present, however, my patients have usually demanded more active interference. After the requisite preparation of the patient, operator, etc., I use a Palmer uterine dilator, the dull ends of which have been ground down to a sharp point. This makes the point of puncture not much larger than that of an ordinary exploring needle. It is pushed into the most prominent part of the hematocele, and the blades are spread. Between them the blades of a Bischoff's rectal dilator are placed and the opening stretched to any desirable extent. I have repeatedly made the opening large enough to introduce my hand into it, if the patient had a large and relaxed vagina, and in these cases was able to explore the entire interior of the sac. After washing out the cavity, it is filled with either iodoform, sterilized or sublimate gauze. The latter is left *in situ* for two or three days, and an ice-bag is applied over the abdomen, and thereafter the dressing is changed every two or three days, or even every day, according to indications, and the cavity allowed to close down gradually. In one instance I had a serious hemórrhage from the point of puncture, but this occurred in April, 1886, when I used a pair of scissors with which to both puncture and dilate. Since then I have had no serious mishap, although in 1889 I had a case in which there was continuous bleeding from a torn vaginal vessel, lasting more than two days. Dr. Von Ramdohr assisted me in this case, and it required considerable search before the vessel was found and sutured. I am not satisfied with the making of a small aperture in these cases, because such openings close too rapidly, making the subsequent dressings too painful. The important point is that the opening should not be made with a cutting instrument, but with one which will gradually stretch the vaginal puncture. The healing process I have found to take from two to eight weeks, according to size of cavity.

A NEW, PRACTICAL DISINFECTANT MATERIAL.

By CHAS. T. McCLINTOCK, M.D.,
OF DETROIT, MICH.

SEVERAL years ago[1] I published the results of some studies on the germicidal value of corrosive sublimate. Geppert, Abbott, and others had shown that sublimate was not as powerful a germ destroyer as most persons supposed. My experiments showed that, exceptionally at least, germs grew after exposure to sublimate solutions as follows: Staphylococcus pyogenes aureus in sublimate 1–1000, twenty-three hours; staphylococcus pyogenes aureus in sublimate 1–100, eleven hours; staphylococcus pyogenes aureus in sublimate, saturated, one hour; bacillus subtilis in sublimate 1–1000, forty-one hours; bacillus subtilis in sublimate, saturated, eighty-five minutes; swine-plague in sublimate 1–200, one hour; typhoid germs in sublimate 1–1000, one hour; germs in feces in sublimate 1–1000, twenty-four hours; germs in feces in sublimate, saturated, twenty-four hours.

I said, furthermore: "However, the proof that sublimate is not a good germicide is no proof that it may not be valuable as a disinfectant. If my interpretation of its action be correct, it follows that a germ treated with sublimate, and possibly with solutions more dilute than 1 to 1000, unless, perchance, it gets into the blood or is exposed to very exceptional conditions, is powerless to grow; that is to say, it is probable that a spore of subtilis or anthrax treated with sublimate 1 to 1000, and then thrown on the soil or into water, will not germinate, owing to the fact that the capsule of sublimate surrounding it is not removed." I pointed out the mistake of the earlier experimenters in concluding that the germs were dead because there was no growth on culture media. I then gave the following probable explanation of the failure of sublimate to kill the germs, although apparently doing so: "Many germs have a gelatinous envelope, often seen in old cultures. The sublimate chemically unites with and coagulates this envelope, and so shuts itself out from the germ cell. There is probably an exact similarity here to the case where spores survive for months in absolute alcohol. Absolute alcohol is immediately fatal to protoplasm, and the only explanation we can offer for the facts is that the alcohol does not reach the interior of the germ cell. Now, if these germs after treatment with sublimate are transferred to gelatin, agar, etc., they do not grow, although many of them at least may still be living. If by appropriate means the sublimate coagulum surrounding the germ is removed, it will grow (provided the exposure to sublimate has not been too long)."

Believing that the failure of sublimate as a germicide was chiefly due to the fact that it coagulated albumens, I undertook some experiments to determine if this coagulation could be avoided and the solution be made to retain the poisoning power of the mercury salt. It is well known that alkalies tend to dissolve albumens and to prevent their coagulation either by heat or chemicals, but the most valuable germicides of the mercury salts, the biniodid and bichlorid, are precipitated and rendered inert by the alkalies. It then occurred to me that in a double salt of mercury and some other metal it might be possible to find a compound that would not give up its mercury to a weak alkali. I tried many combinations with mercuric chlorid, but in vain. I did find with one of the sulphites a combination that worked satisfactorily when freshly made, but on standing in the air the sulphite was changed and the mercury precipitated by the alkali. Turning to the iodids, I was more successful. For example, a solution of the double salt of mercury and potassium iodid will permit the presence of a weak alkali without precipitation of the mercury. In such a solution albumens are dissolved; further, nickel and steel are protected by the alkali from the action of the mercury. This seemed to be what I was looking for, as it was a germicide more active than mercuric chlorid or iodid that would not tarnish instruments. But, after making hundreds, even thousands, of experiments with the material, it was not satisfactory. The trouble seemed to be in the amount of alkali needed: if too much was used, the mercury was precipitated; if too little, the metals were attacked. If the correct amount was employed at the outset, some of it might be used up, uniting with albumens, for example, in disinfecting the skin.

I next took advantage of the well-known fact that when neutral soaps are dissolved in water they are gradually decomposed into acid soaps and free alkali. By combining my mercury salt with the soap, when this was dissolved, I got a gradually increasing amount of alkali, sufficient to replace any used up by albuminous or other bodies present in the field of experiment. But some soaps, I found, liberated the alkali too rapidly, others too slowly. The amount of alkali and the rate of liberation depend in part on the nature of the oil from which the soap is made; also, to some extent, upon the amount of glycerin, free alkali, fatty acids, unsaponified fat adulteration, etc. After a long series of experiments to obtain the right kind of soap, the proper amount of the mercury salts, etc., I obtained a combination that appears to be fairly satisfactory. At first I used a soap containing one-half per cent. of mercuric iodid; but, by varying the composition of the soap, I found I could use one per cent., and later on two per cent., of the mercury salt. I give here the results of a few of the experiments made with this material; also, some experiments made at the same time with other disinfectants. A word as to the method used in making the tests. The germs used were anthrax spores, typhoid, cholera, diphtheria, and staphylococcus pyogenes aureus. Most of the experiments were with the common pus germ, staphylococcus pyogenes aureus, as this is the organism against which our attempts at disinfection are usually made. Several different recently-isolated cultures of this germ were used. In some series of experiments, in order to avoid the danger of carrying along on the platinum wire sufficient of the disinfectant to act as an antiseptic in the culture medium, I proceeded as follows: The germs were placed for a given time in the solutions to be tested, then one or more loops were removed to a tube containing five cubic centimeters of sterile water, to which had been added two or three drops of ammonium sulphid. In this method, introduced by Geppert, any of the disinfectant carried along in the drop of fluid clinging to the platinum loop is precipitated. From this second tube two loops were then transferred to a third tube of bouillon or, in some of the experiments, melted gelatin. If after some days in the incubator the tubes showed no growth, they were then inoculated from the original culture used in the experiments, in order to show whether germs would grow.

---

[1] "Corrosive Sublimate as a Germicide," MEDICAL NEWS, October 1 and 8, 1892.

In some of the series mere dilutions were used, the germs after being in the disinfectant being transferred to a tube of bouillon, and from this tube a second one was inoculated.

TABLES.

1-PER-CENT.-ANTISEPTIC-SOAP SOLUTION, CONTAINING 1–5000 MERCURIC IODID.

Germ.	1 Min.	5 Min.	15 Min.	30 Min.	60 Min.
S. p. aureus	0	0	0	0	0

ANTISEPTIC SOAP; MERCURIC IODID, 1–2000.

Germ.	1 Min.	5 Min.	15 Min.	30 Min.	60 Min.
Anthrax spores.....	0	0	0	0	0

The antiseptic soap was tested after it had been exposed two months to sunlight. The results were as good as with the fresh material. While, in the above tables the results are not entirely uniform (as would be expected by any one familiar with the testing of disinfectants), it will be seen that in but a single case (this is true for the thousands of experiments as well as for the examples shown above) did any one of the germs tested—typhoid, diphtheria, cholera, aureus, and anthrax—survive one minute when the solution was as strong as one per cent.

There are a number of antiseptic soaps offered for sale. I have examined several. Most of them are merely soap to which a certain amount of corrosive sublimate has been added. Any tyro in chemistry ought to know that this is an incompatible mixture. As soon as the soap is dissolved it begins to break up into free alkali and acid soap, and the alkali will at once precipitate the mercuric chlorid. Certain of the antiseptic soaps are combinations of the phenols, thymol, etc. I have tested most of the soaps of this character now on the market. Tested against the pus germ, staphylococcus pyogenes aureus, these gave, even in five-per-cent. solutions, growths up to 15 minutes, or as long as tested.

As said before, this soap does not attack nickeled or steel instruments under any ordinary exposure. They may be boiled in a strong solution of it without harm. If left in the soap solution for some days, however, the instruments may rust. For the past six months I have used this soap exclusively for shaving and disinfecting the site of injection and operation in a number of horses used in the production of antitoxin. During that time the percentage of abscesses and suppurating wounds has been less than one-half of what it was when mercuric chlorid and carbolic acid were used. The razors used have never shown the least effect from the mercury salt. It seems to me that the material should be of value to the surgeon, and particularly useful to the gynecologist and obstetrician, as it will serve both as a disinfectant and lubricant for hands and instruments. As a general disinfectant for physicians' use after visiting cases of infectious diseases, after examining cases of gonorrhea, syphilis, tuberculosis, etc., it should have a place. Several specialists are testing it in skin diseases, and it may be of service, owing to its power of dissolving albumens and because it is so penetrating, where mercuric chlorid would coagulate and shut itself out. I have used it in one case of gonorrhea as an injection with apparent success. Only a few detailed experiments are given in the tables, although I have made some thousands with this material. I have also asked several friends of mine, working bacteriologists, to test the material. Their results are substantially the same as mine.

In testing this soap, one may be misled as follows: A loop is transferred from the soap solution that has been inoculated with the germ. This is placed in bouillon or gelatin. After some hours the medium becomes cloudy and looks as if it contained a vigorous growth of germs. But this is a deception. The cloudiness simulating a germ-growth is due to the decomposition of the soap and a partial precipitation of the same by the sodium chlorid present in bouillon. An inoculation from this tube into a second will settle the question.

Conclusions.—(1) In proportion to the amount of antiseptic contained, this soap is at least five times as strong as any known germicide. A one-per-cent. solution of the soap, 1–500, of mercuric iodid, is at least equal to 1–1000 mercuric chlorid. (2) As it would ordinarily be used, it is at least as strong as any germicide in common use; *i.e.*, I believe that if a wet cake be rubbed over the hands, the layer of soap next the skin will be at least a one-per-cent. solution, and, as the tables show, this is at least as strong as 1–1000 mercuric chlorid. (3) It does not coagulate albumens or attack nickeled or steel instruments. It does not seem to have any action on lead, and so will not injure waste pipes. (4) It will attack silver and aluminum instruments.

HYDROTHERAPY IN TYPHOID FEVER.[1]

By FRANK H. DANIELS, M.D.,
OF NEW YORK.

The use of water externally is one of the oldest therapeutic measures of which we have a record in medicine. Not wishing to go deeply into ancient history, let me simply say that Hippocrates laid down rules for the use of this agent in both acute and chronic disease. Later it was used extensively in Rome; and even the Emperor Augustus bears testimony to its advantages in his own person. For a time it fell into disrepute or rather, to use a famous expression, into innocuous desuetude, only to be resurrected by Floyer, an Englishman, in 1697. Since then it has had its champions and opponents in all parts of the world, until to-day it is universally recognized by those who are acquainted with its scientific use as one of our most potent agents in the treatment of all forms of disease.

---

[1] Read before the Harvard Med. Soc., of New York, March 27, 1897.

Currie, a century ago, spoke of its great value in all acute fevers, and his work was translated into several foreign languages. Priessnitz, the Silesian peasant, early in this century popularized the treatment, and his name has now become closely associated with hydrotherapeutic procedures. It remained for Brand of Stettin, however, in his work which appeared in 1861, to put hydrotherapy, as far as typhoid fever is concerned, on a proper scientific basis. He claimed that full baths at a temperature varying from 80° to 65° F., would reduce the mortality of typhoid fever to a lower point than any other known method of treatment; and, further, that if the baths were resorted to early enough, and carried out properly, every case ought to be saved.

In order to fully appreciate the value of this method of treatment, let us first consider the effect of cold water upon the human body when applied externally. The first effect of immersion makes itself felt on the peripheral circulation, and the terminal nerve filaments in the skin. Under the stimulus of the cold the cutaneous blood-vessels contract, and this is followed later by relaxation. This naturally forces the blood into the other organs of the body and helps thereby to restore the tone of the general circulation. The shock to the terminal nerve filaments is conveyed to the central nervous system and thence reflected to various parts of the body. The effect on respiration is to cause at first a gasping followed by a deep inspiration. These spasmodic efforts soon give way to a normal but deepened rhythm. The stimulating effect on the heart is shown by Winternitz's experiments. He found that cold applied to the surface at first increases the pulse-rate, which is immediately followed by a diminution. The urine is increased in quantity and its specific gravity lowered.

To the direct stimulation of the central nervous system and the heightened tone of the circulation, is attributed the beneficial effects of the cold baths on the nervous symptoms in typhoid fever. Whereas, the blood has been circulating sluggishly in dilated, inelastic vessels, it is now forced through vessels which have recovered their tone, and it is enabled to reach all parts of the body. The deepened respiration allows more oxygen to be taken up by the blood, and the result must be an enriching of the blood supply to the detriment of the toxins circulating therein. No such beneficial effect would be obtained if the cold baths were given without continued friction to the surface of the body. The relaxation following the original contraction of the blood-vessels, due to the sudden contact with cold water, would then remain constant, and the result would be depressing instead of stimulating to the general circulation. The friction employed is a constant irritation, both to the peripheral cirulation and the terminal nerve filaments in the skin; and by this means we accomplish the advantage claimed for this method of treatment.

Flint says in the fifth edition of his "Practice of Medicine": "It must be admitted that the known resources of therapeutics do not afford reliable means for the arrest of typhoid fever, nor even for shortening the duration of the febrile career. In the present state of our knowledge the most important object of treatment with reference not to arrest or abridgment of duration, but to severity and danger to life, is the reduction of the body heat. There is ground for the belief that in typhoid and other fevers, where there is continued hyperpyrexia, the severity and danger to life are due directly in a greater or less degree to the increased heat of the body." If this statement of Flint were correct, the Brand treatment of typhoid fever would have no reason for existence, as none of its supporters claim that it has any marked influence upon the body temperature. They would acknowledge the truth of his first statement, namely, that we have as yet no reliable means for its arrest or even for shortening the duration of its febrile career. But the claim is made and substantiated, I believe, that this treatment enables the patient to bear the continued high temperature without danger or bad result.

The real danger in typhoid fever results from the presence of the poison which circulates in the blood and which, without doubt, gives rise to the peculiar complex of symptoms recognized and known as the typhoid state. This comprises the symptoms due to some profound influence exerted principally upon the nervous system. The low muttering delirium, the deafness, dry tongue, tympanites, diarrhea, rapid pulse, and wakefulness, are all symptoms which one thinks of immediately when the word typhoid is mentioned; and any treatment that will relieve these symptoms when present, or will prevent them from appearing, must be recognized as a distinct advance on the methods hitherto employed. It is not claimed that the duration of the disease is shortened, and it is doubtful if complications are avoided, though in my opinion some of the latter certainly are. As a method of treatment, I do not think that it is an ideal one, for it does not reach the cause of the disease, nor does it attempt to do so; but, until we have a method which will have the same effect on the direct cause of the disease that quinin has on the *plasmodium malariæ*, it will remain as the most satisfactory form of treatment. To be sure, in private practice it gives rise to a great deal of trouble and expense. A suitable portable bathtub must be procured, and two intelligent nurses must be in attendance to carry out the treatment properly. This is one great objection in cases occurring in families of moderate means, living in small apartments, and such cases ought to be treated in hospitals, particularly if the patient is a heavy adult.

Especial attention must be given to the cardinal points of the treatment: These are, first, early institution of the baths; second, the water should be at a temperature of 65° to 70° F.; third, constant friction in the shape of rubbing must be employed while the patient is in the bath; fourth, the baths should be of fifteen-minutes' duration and repeated once in three hours as long as the temperature reaches 103° F. by the rectum, or as long as the so-called typhoid symptoms continue, even if the temperature is lower. Of these, the third rule, *i.e.*, the continued rubbing while in the bath, is the most important. If these cardinal points are carefully adhered to, no bad results will follow; on the contrary, the patient will feel a sense of quiet and comfort after the baths which no drug can give. A complaint of chilliness on the part of the patient is not enough to warrant his removal from the bath before the expiration of the fifteen minutes. If this chilliness, however, is accompanied by continued chattering of the teeth, or by cyanosis of the face or lips, it is better to remove him at once. An accelerated pulse is also a danger signal, but a small pulse is not. It is best to precede each bath by a dose of whisky or brandy, half an ounce being an average dose. The shivering is lessened if this is given ten or fifteen minutes before each bath, so that it can be absorbed and have some effect on the peripheral circulation. I know of but two contra-indications to the use of these baths—severe intestinal hemorrhage and perforation of the bowels, in both of which complications quiet is of the utmost importance. Pregnancy and menstruation are not injuriously affected by the baths. I will show you later the chart of a female patient, seven months pregnant, who was treated in this way and who gave birth to a child at term. It has seemed to me that relapses, mild in character, are more common after bathing, but a longer experience with this method may result in a modification of this belief. Complications are certainly less severe.

I will not weary you with statistics as to the results of the different methods of treatment, but will cite a few only. Delafield found a mortality of 24.66 per cent. out of a total of 1305 cases treated in New York hospitals during the years 1878–1883. The German Hospital, Philadelphia, reports 64 cases treated from February 1 to November 4, 1890, by the Brand method without death. Brand himself published the following statistics in the *Deutsche Medicinische Wochenschrift* during 1887: Jürgensen of Tübingen treated 217 cases, with one death; Vogl of Munich, 221 cases, 6 deaths; Military Hospital, Stralsund, 1877–1882, 257 cases, 1 death; Military Hospital, Stettin, 186 cases, 3 deaths; Brand, private practice, 342 cases, 1 death; a total of 1223 cases, with but 12 deaths, a mortality of 1 per cent. Brand's own results were amazing, only one death among 342 patients treated. Not one of these twelve deaths occurred in a patient that came under treatment during the first five days of the disease. And this is a point on which Brand lays great stress, namely, the early institution of the baths. Most of our hospital patients do not come under treatment until they have been several days ill, and even amongst our private patients it is not so easy to make a diagnosis at that early period in all cases. The statistics quoted above are mainly from military hospitals, where the patients are under proper supervision from the beginning. Still, not even their results can equal those of Brand in his private practice, in which only one patient out of 342 was lost.

It has been claimed that in true typhoid the temperature drops but little after a Brand bath, while in other acute diseases there is a greater drop. This has even been mentioned as a possible diagnostic point, but I have not been able to satisfy myself that this observation is well founded. Now that we have the Widal or blood-serum test for typhoid fever, we are not dependent on any other method of diagnosis, provided the reaction takes place early enough in the disease to be of value. The Brand treatment really needs some such method of positive diagnosis as this promises to be; for it has been proved beyond doubt that it is of the utmost importance to begin the treatment as soon as possible after the patient falls into our hands in order to accomplish the best results.

How slight the change in temperature may be after the Brand baths is well shown by a patient treated during my service last autumn at the J. Hood Wright Memorial Hospital. During seven days fifty baths were given, and there was an actual rise of temperature after each. It is our invariable custom to take the rectal temperature of our patients just before the bath, immediately after, and again half an hour later. In this way we are enabled to observe quite accurately the influence of the baths upon the body temperature. In the case of another patient, however, who died on the sixth day after admission (the fifteenth day of the disease), the drop in temperature after the baths was most marked, varying from 2.8° to 4°. This case was complicated by pneumonia. Another patient, who was seven months pregnant, received twenty-six baths. She eventually recovered and was delivered at term. The fetal heart-beats were counted daily and varied from 180 per minute, when the disease was at its height, to 140 when the patient left the hospital. One of our nurses, twenty years old, contracted the disease, undoubtedly in the wards, and died from an attack of bronchopneumonia during the sixth week. She came of a tuberculous family, was herself extremely anemic, and an examination of her blood showed only thirty-five per cent. of hemoglobin. She received ninety-five baths in all, given over a period of seventeen days. The symptoms attributable to the typhoid infection were subsiding, when the bronchopneumonia invasion took place; and although her temperature for the first ten days of treatment varied from 104° to 106° F. in the rectum, she was quite comfortable, and did not become delirious until the beginning of the bronchopneumonia.

The last case I will cite is that of a patient whom I have no doubt whatever was saved by the application of the Brand baths and cold affusions to the head and shoulders. He was twenty-seven years old, unmarried, and lived in a boarding-house. I first saw him October 20, 1896, when he had an attack of *grippe*. In four days his temperature became normal and he said that he felt perfectly well. Nine days later he appeared at my office with a mouth temperature of 104° F. and a pulse of 120, when a diagnosis of typhoid fever was made. Forty-eight hours earlier he had taken a long ride on his bicycle. For eleven days he was treated at home, but he grew constantly worse in spite of all that I could do for him. I had advised his early removal to the hospital so that he might be bathed; but objections were made by a relative. It was impossible on account of the expense to bathe him at home, as two male nurses would have been necessary. The day before he went to the hospital his condition was as follows (and I might say it was only because his condition was so desperate that his friends gave their consent to his removal): Temperature by the rectum, 105° F.; pulse 150, weak and irregular. Facies drawn, skin suffused, tongue dry, and abdomen distended and tender. He had diarrhea, with involuntary evacuations, subsultus tendinum was most marked, and delirium was active at times, but continually muttering. On admission to the hospital he was immediately given Brand baths and cold affusions. He eventually recovered. This case shows better than any other I could present the advantages of this method of treatment. Begun as it was late in the course of the disease, *i.e.*, at the end of the second or the beginning of the third week, it still was efficacious. I am convinced that early bathing here would have warded off these nervous symptoms, and the entire course of the disease would have been less severe. His temperature was at no time after admission to the hospital very high, but the patient was certainly thoroughly infected with the typhoid poison. The cold affusions were used at a temperature of 65° F., and on the second day his mental condition was better. Six days later his tongue was moist, there was but little subsultus tendinum, the abdominal distension had disappeared, his bowels had to be moved by injections, and he was passing sixty-one ounces of urine in twenty-four hours. From that time on the case was similar to one of ordinary typhoid, but later the patient developed an abscess over the sacrum which retarded his convalescence somewhat, and which was doubtless due to an infected bedsore, which originated before he entered the hospital.

CLINICAL LECTURE.

TRICUSPID REGURGITATION; SENILE GANGRENE; THE DIAGNOSIS OF TYPHOID FEVER BY THE AGGLUTINATION TEST.[1]

BY H. A. HARE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE.

THE first patient that I show you is, as you notice, somewhat cyanotic. His respirations are a little more labored than is normal, and he sits up in bed rather than reclines. His chest is deep and well developed, his neck is that of a powerful man, and his face shows that he has been much exposed to the weather. When we examine his lips a little more closely, we notice that in them the dusky color of his face becomes more marked. His finger nails are also blue and livid. On closer inspection we find, also, that the jugular vein, particularly that upon the right side, is pulsating, and that this pulsation occurs with the systole of the heart, which indicates that the right ventricle as it contracts not only forces blood into the pulmonary artery, as it should do, but that regurgitation takes place into the right auricle, and from there into the right jugular vein. In examining the jugular vein in any case of heart disease to determine whether or not pulsation is present, you must always be careful to avoid mistaking a transmitted impulse from the carotid artery to the tissues in the neighborhood of the vein for true jugular pulsation. In this case, however, the pulsation is so marked that there can be no doubt as to its causation. The symptoms which the patient presents are chiefly those of cardiac dyspnea, and we naturally proceed immediately to an examination of his heart for the purpose of determining positively what the cause of his distress may be. On listening to the apex, the spot to which we always first direct our attention in studying lesions of the heart, I hear a murmur, systolic in point of time, or in other words, occurring with the first sound of the heart, and this murmur is of a peculiar metallic sound and rather short and sharp. However, when I listen over the aortic cartilage I hear this murmur even more clearly than I did at the apex, and therefore the first impression might be that this is a case of aortic rather than mitral disease, particularly if it is borne in mind that a murmur is usually loudest at its point of origin. But the jugular pulsation makes me suspect that the man has something else than aortic disease, and that the only reason I hear the murmur loudest over the aortic area is because I have approached nearer to its seat of origin, namely, the tricuspid valve. When I place my stethoscope over the fourth interspace on the right side, I hear the murmur more clearly and more definitely than before. Indeed, it seems as if the murmur was transmitted directly to my ear from its point of origin. It is evident, therefore, from the symptoms and from the location and character of this murmur that the patient is suffering from tricuspid regurgitation. This becomes still more certain when I find that the murmur is clearly transmitted to the back upon the right side. I can also see that there is marked pulsation in the hepatic area, and, as you know, true hepatic pulsation is never present except in cases of tricuspid regurgitation. It must be remembered, however, that in some cases when the heart is acting powerfully and the liver is somewhat enlarged, and particularly if the heart is displaced somewhat to the right, the ordinary cardiac impulse may be transmitted to the liver. In order to exclude such a possibility in this case, I place one hand under the floating ribs anteriorly and the other hand over the same ribs at the side, and doing so I find marked expansile pulsation of the organ. An entirely different sensation is imparted to my hands from that which would occur if the liver were simply jarred by a transmitted cardiac impulse.

---

[1] A Lecture delivered at the Jefferson Medical College Hospital, February 8, 1897.

One of the most annoying symptoms from which this patient suffers is excessive cough, and, on listening to his chest, particularly at the base on both sides, posteriorly, I find a large number of moist râles, which are due to the fact that the pulmonary circulation is impaired, owing to the failure of the tricuspid valve, and as a result he has a certain amount of stasis or congestion of the lungs. At first glance it would appear that the first thing to do for the relief of the patient is to administer some narcotic or sedative that will allay to a great extent this excessive cough. It renders his condition most pitiable as it gravely interferes with respiration and circulation, and during his coughing attacks he becomes very cyanotic and oppressed, the jugular veins swelling to such a degree that it seems as though they would burst. Although we are tempted for these reasons to administer such drugs, we are forced to bear in mind, on the other hand, that these remedies, by stopping the cough, may prevent the patient from expelling from his lungs the mucus which gradually accumulates in them, and under these circumstances he would rapidly drown in his own secretions.

When he entered the wards his breathing was far more labored and the action of his heart was irregular and feeble. If I had given him digitalis in the presence of an arterial pressure already somewhat high, I would have stimulated the heart, but at the same time increased the labor of this organ by increasing the arterial pressure. I ordered for him instead of digitalis, strophanthus tincture in 5-drop doses and $\frac{1}{100}$ of a grain of nitroglycerin three times a day, and he is greatly relieved.

You must understand that the condition of tricuspid regurgitation is a comparatively rare condition, and many of you may pass through a lifetime of practice without meeting with a case. When you do meet with one it will usually be secondary to disease of the mitral orifice or to the presence of emphysema or some other process in the lung which interferes with the transmission of the blood from the right to the left side of the heart. This obstruction results in dilatation of the right ventricle and failure of proper approximation of the tricuspid leaflets and consequent regurgitation. Very much more rarely will the condition of tricuspid regurgitation be primary, as it is in this instance, for rheumatism rarely involves these valves primarily, and in this patient we have sought in vain for any history of rheumatism, or strain, or for other cause which could have resulted in the development of the lesion.

The second case that I show you is also one of tricuspid regurgitation, which is, however, apparently secondary to a mitral regurgitation, and which is almost as interesting as the one we have just examined. In this case the murmur is not so loud, there is no pulsation of the liver, the jugular veins are not markedly distended, and the condition of the patient is moderately comfortable.

The third case is one of senile gangrene. The patient was admitted to the wards about four weeks ago with dry gangrene involving the little toe of the left foot, a distinct line of demarcation having formed just where the toe joins the body of the foot. At this time his pulse was exceedingly feeble, and an examination of his blood vessels showed them to be markedly atheromatous. His nutrition was fairly good for an old man of sixty-three, and aside from his inability to walk, and some paroxysms of severe pain in his leg about four inches above the ankle, he was otherwise in good condition. There were no abnormal heart sounds.

It was evident that we had to deal with a case of senile gangrene, because of the atheromatous blood vessels and feeble pulse, and for the reason that an examination of the urine by the resident physician failed to demonstrate the presence of albumin or sugar. In this connection the case is also of interest as illustrating the necessity of frequently examining the urine when the diagnosis is obscure, for, about ten days later, an examination revealed sugar, and another quantitative examination made a few days later revealed it again in small amounts. It is only proper for me to mention the fact that the man had no other symptoms of diabetes than glycosuria, which of itself is not, of course; absolutely pathognomonic. He had no thirst, no excessive hunger, no itching, and no boils. The disease gradually progressed, notwithstanding stimulant treatment, but his pain markedly decreased. His third toe next gradually became gangrenous, and forty-eight hours ago, in the course of twelve hours, the entire foot, with extraordinary rapidity, became gangrenous almost to the ankle, the rapid process being a moist gangrene, in contrast to the dry or shriveling gangrene which first developed. Simultaneously with this sudden increase in the local disease the patient's temperature rose to 104½° F., and he speedily became partially comatose, answering when sharply spoken to, but sinking into slumber before he had finished his reply to the question. A few hours later, as it was seen that his coma was deepening, I decided to perform upon him what the French physicians have recently been so enthusiastic about, namely, intravenous washing of the blood, which consists in introducing a canula into a vein of the arm, and injecting very gently through it, by means of a fountain syringe, a normal saline solution, which is supposed to wash the blood of poisons and cause their elimination by the kidneys. Shortly before performing this operation I found that the patient's arm when raised remained in the position in which it was placed, or, in other words, he had developed a spastic rigidity of the muscles, and while the injection was being given he had a tonic convulsion, in which his respirations rose to sixty a minute, and were slightly Cheyne-Stokes in character. His pulse became almost extinguished, although during the early stages of the injection it was remarkably strong and full. The convulsion soon ceased, and in the course of half an hour the patient had a very profuse sweat, which saturated the bedclothing. On leaving him for the night I informed his wife and children that I did not expect him to survive more than an hour or two, but to my great surprise yesterday morning I found him quite conscious, encouraged about himself, and fairly bright. The fever had disappeared, but the gangrenous process was rapidly extending up the leg, and his feeble pulse and irregularly acting heart told me that the end was not far off.

The fourth case is of peculiar interest, not only because of the difficulties in its diagnosis, but because a comparatively new method of diagnosis has decided what the condition of the patient is. She is nineteen years of age, a light mulatto, who has a long history of general debility and anemia. A little over two weeks ago she had an attack of dizziness followed by fever, these symptoms being preceded for a number of days by general wretchedness. Her temperature has at times risen as high as 104° F., and has been controlled by either bathing or sponging, usually the latter. She has been obstinately constipated from the first, and her stools have had nothing characteristic of typhoid fever about them. There have been no spots on the abdomen, and I have not found any considerable enlargement of the liver or spleen. There has been only a moderate amount of tympanites and the tongue has not at any time been distinctly typical of typhoid. The fact that she seemed to be in a typhoid state, however, rather pointed to the presence of enteric fever. An examination of her abdomen shows it to be but slightly tumified, the skin being perhaps a little more dusky than is natural. What is more important is the fact that the skin here is rough and appears like *cutis anserina*, a condition which I have often noticed in cases of tuberculous peritonitis, although it is of course in no way characteristic.

With the idea that it might be a case of tuberculous peritonitis, in which case an operation would be demanded, I asked Dr. Keen to see the case in consultation with me and we decided in view of its uncertainty that we had better wait until other symptoms developed, as there did not seem to be the fluid present in the abdominal cavity that is usually found in many cases of this disease. The decision as to the character of the case was determined, however, by what is known as Widal's agglutination or clumping test, which rests upon the fact that the bacilli of Eberth, which, as you know, are the characteristic micro-organisms of typhoid fever, cease their movement and become agglutinated or "clumped" when brought into contact with the blood serum of typhoid fever patients. I asked Dr. J. C. Da Costa, Jr., one of the assistants in the medical clinic, to make this test for me, and he reported that agglutination took place in less than a minute. We have decided, therefore, in view of this test, that the patient is suffering from enteric fever and not from tuberculosis. That this test is reliable is proved not only by the reports of Wyatt Johnson of Montreal, and Greene of Minneapolis, but by numerous other clinical observations both in this country and abroad. It is interesting to note, however, that in one instance both Professor Coplin and Dr. Da Costa have seen this agglutination result in the case of a patient who was not suffering from any symptoms of typhoid fever but who had a double aortic murmur. This may have been due to the fact that the patient at some comparatively recent period had recovered from typhoid fever and therefore gave the reaction.

CLINICAL MEMORANDA.

A CASE OF TUBO-ABDOMINAL PREGNANCY, WITH DELIVERY OF A LIVING FETUS AT THE SEVENTH MONTH.[1]

By EDWARD A. AYERS, M.D.,
OF NEW YORK;
PROFESSOR OF OBSTETRICS AT THE NEW YORK POLYCLINIC;
VISITING PHYSICIAN TO THE MOTHERS' AND BABIES' HOSPITAL.

MRS. G. R. was referred to me by her physician, Dr. Thomas D. Pinckney of Williamsbridge, N. Y., who gave the following history of the case: The patient was married fifteen years ago, having a child normally a year later. A second child was born a year afterward, following which the mother suffered from peritonitis and was confined to bed for three months. Her lochial discharge continued for ten weeks. She menstruated every three weeks after getting up, and did not become pregnant again until seven years had elapsed. She then had an instrumental abortion performed when she believed herself five weeks pregnant. Considerable hemorrhage ensued, but no special reaction of an inflammatory character seems to have occurred. Menstruation began in three weeks. About five years later she again became pregnant and a second abortion was accomplished at five weeks gestation. The last abortion was followed by fever, pain, and the expulsion of "pieces of flesh." The flow ceased in two weeks. The patient said that she never felt well afterward. She had "an uncomfortable feeling in the lower part of the abdomen, chiefly on the left side." This was in February, 1896. Menstruation returned and was normal in character. During April her menstrual flow was very scanty, but it continued for eighteen days. The discharge was brown, "like coffee stain." She had a slight flow May 1st. During that month she began having sharp, cutting pains in the left lower part of the abdomen, which were sometimes followed by fainting spells and always by great exhaustion. The pain, though more dull in character, continued until August. She felt life August 13th. She had been growing larger, with a feeling of tightness in the abdomen when on her feet.

---

[1] Read before the Obstetrical Section of the New York Academy of Medicine.

I first saw the patient in consultation with Dr. Pinckney, on Saturday, October 31, 1896. She was pale, emaciated, and the face wore an anxious expression. She had had morphin at times for a considerable period, and the mouth and tongue were dry. She was suffering severe pain, due to the fetal movements. Dr. Pinckney had heard the fetal heart, to the right of the umbilicus, some time before.

The patient was removed to the Mothers' and Babies' Hospital that afternoon. After free catharsis had been obtained, I made an examination under chloroform. The abdomen appeared enlarged to the size of a five or six-months' pregnancy. There was some slight bulging in the left lower quadrant, and along the right middle and upper quadrants. The fetus was clearly mapped out as lying in a line parallel with the maternal vertebræ, and with its dorsum to the right, the entire body being chiefly in the right half of the abdomen. The head was not outlined, the position being determined by the location of the limbs, back, and fetal heart. The fetus did not feel nearer to my fingers than in many normal cases of pregnancy I have examined. The left lower quadrant of the abdomen held a mass that could not clearly be made out. It was neither elastic, cystic, boggy, or firm. While it might be placenta, I could not affirm it. There was no vascular murmur to be heard in or about it. The cervix was soft, spongy, enlarged, and patulous up to the internal os. In connection with the anterior lower segment of the uterus, which felt soft and somewhat elastic, it suggested a pregnant uterus of about five months. The fundus could not be outlined, for reasons shown when the abdomen was opened.

Being able to exclude an intra-uterine pregnancy, the history pointing most emphatically to an extra-uterine gestation, I determined to follow a conservative course, and on November 7th, dilated the cervix, having decided that in any case it was not just to the patient to permit the pregnancy to continue. The uterine cavity was found to be small in extent, and was lined with a soft and easily detached membrane. This was removed and the cavity lightly packed with iodoform gauze. The abdomen was then opened, Dr. J. A. Bodine kindly assisting me, in connection with the hospital staff, and the placenta was found just under the omentum, covering most of the space below the umbilical line, and somewhat to the left. The fetal surface of the placenta lay immediately beneath the abdominal wall, the cord arising from the middle of its upper surface. A layer of blood coagulum covered most of the abdominal contents in front. This was of recent origin, with older clots of a liver-like character lying between the uterus, placenta, and intestines. The head of the fetus lay just behind the fundus. Delivery was accomplished without difficulty, the left shoulder, and then the head and body being born. Under Dr. Mitchell's skilful handling good resuscitation was secured.

The child was lying outside the amnion. The placenta was extremely convex, almost balloon-shaped, with, as I have said, the fetal surface lying uppermost. False membranes bound it on all sides, uniting it to the anterior wall and fundus of the uterus on the right, to the colon posteriorly, and to the peritoneum on the left and lower anterior part. Its vascular supply came from the left Fallopian tube, apparently from the outer half, the pregnancy evidently having started in this tube. Aside from being bound down like a balloon held to the earth, the placenta was quite free above and could be considerably displaced. The hemorrhage caused by its removal was not very great. It weighed one pound, three ounces. The cord was about eighteen inches long. Iodoform gauze was packed in the left lower pelvis and the wound closed up to the gauze. The abdominal operation lasted three-quarters of an hour. The patient suffered severe shock, due chiefly to the great vital depression resulting from her prolonged sufferings. Hot saline injections were retained, and the next morning her condition seemed favorable, but at eleven o'clock she succumbed from general exhaustion.

The uterus was removed *post-mortem*. Its limitations could not be made out by abdominal palpation previous to operation, as it was covered by placenta. Its weight was 11½ ounces; length, 5⅜ inches, and width, 3½ inches. The thickness of the wall through the middle plane was 1 inch, the diameter of the cavity from the external os, 4⅖ inches; the circumference of the body, 9½ inches, and the diameter of the cervix, 1⅝ inches. The placenta was nearly spherical and was 6¾ inches in diameter, 1⅝ inches thick in its thickest part, and weighed 1⅖ pounds when the blood had been removed.

The membrane which lined the uterine cavity was lightly attached to the body wall. I have examined sections of it under the microscope, and it proves to be distinctly decidual, though possessing some of the appearances of chronic endometritis, to the extent that there are still remnants of utricular glands, rather a diminution in number, while the columnar epithelia have lost their normal regularity of shape and arrangement, being desquamated, disintegrated, or supplanted by connective-tissue corpuscles. Large areas of the membrane were composed entirely of characteristic decidual cells, normal in structure and arrangement.

I wish to call attention here to a paper published by me in 1892, on "The Decidua in the Diagnosis of Extra-uterine Pregnancy."[1] The conclusions arrived at from my investigations were: In extra-uterine pregnancy the endometrium generally changes to decidua; decidual tissue is pathognomonic of pregnancy; portions of the endometrium may be obtained with the curette, examined with the microscope, and decidual tissue recognized if present; such tissue may be a remnant of an abortion, a part of the decidua surrounding an ovum, or due to an extra-uterine pregnancy; the use of the microscope in connection with the clinical history will determine to which variety the specimen belongs, and if to the third, will confirm the presence of an extra-uterine gestation.

That this last conclusion, if true, is of very great importance in connection with the diagnosis of uterine abnormalities, cannot be denied. The history of extra-uterine gestations is one of brilliant diagnoses and operations much mixed with false diagnoses or no diagnoses. The statements made in my paper are gradually receiving the approval of investigators. Webster of Edinburg practically incorporates my arguments in his excellent work on "Ectopic Pregnancy," published in 1895, adding at the end: "Ayers has carefully considered this subject, and is of the opinion which I have given above, *viz.*, that decidual cells are alone due to the influence of pregnancy." Strahan, in his work on "Extra-uterine Pregnancy," which won the Jenks prize, says: "The lining mucous membrane also undergoes development into a true decidua. Indeed, it has been suggested by an authority that we should dilate the cervix and ascertain the presence or absence of the decidua as a crucial

[1] *Amer. Jour. of Obstet.*, vol. xxvi, No. 3, 1892.

test as to the existence of extra-uterine pregnancy. The hint might possibly prove useful, as in case it turned out to be a normal pregnancy the worst that could result would be an abortion." As this publication shortly antedates my own, the author evidently does not refer to my work, and it would therefore seem that I was not the first to propose the plan. I do not know, however, to whom he refers. It is satisfying, at any rate, that the procedure is approved of.

In the majority of cases in which an extra-uterine pregnancy is suspected a laparotomy will be indicated. When there is doubt as to the correctness of the diagnosis of either intra- or extra-uterine pregnancy I think a curettement for the purpose of substantiating the diagnosis is justifiable, even if, in the former case, it subjects the patient to the possibility of an abortion. According to Toth (*Arch. für Gyn.*, Bd. iv., H. 2) rupture of the tubal sac in extra-uterine pregnancy occurs in 70.3 per cent. of all cases, mostly during the first three months of gestation. Schauta puts the mortality in non-operated cases as 68.8 per cent., and in operated cases as 23.4 per cent. The dangers from the production of abortion in normal pregnancies, brought about in the effort to make a diagnosis of suspected extra-uterine pregnancy, are slight, and in any event should not weigh against the terrible liabilities that lie in the path of overlooked extra-uterine gestations.

Curettement in cases of extra-uterine disease or preg-

Fig. 2.

nancy is liable to precipitate accidents. The *American Journal of Obstetrics* for November, 1896, reports Hofmeier and Löhlein as having observed the formation of an hematocele following curettement, which in some cases proved fatal. Hammerschlag reports a case followed by abscess of the parametrium. In preparing for a curettement of this sort, therefore, we should likewise prepare for a laparotomy, which, as in my case, could be performed at the same sitting. In the majority of cases a microscopic examination of the endometrium will not be necessary to one who is familiar with the various appearances of the lining uterine membrane.

I had hoped when I began this report to be able to present the infant alive. It lived three weeks, and after improving in appearance, losing to some extent the wrinkled, little-old-woman skin, and gaining some few ounces in weight, began to lose its nursing ability, and died from inanition. At the time of its delivery it showed the effects of lying in a surrounding medium that, while soft, was not like the amniotic fluid of a normal pregnancy. From the appearance of the placenta the fetus must have been without an amniotic covering for many weeks, as the amnion was everted, turned down, and adherent to the uterus, intestines, and peritoneum, the fetus lying amongst the intestines along the right side of the abdomen. The left foot was bent inward, resembling a talipes varus. The head, which lay between the fundus uteri and the promontory of the sacrum, was pressed somewhat out of shape, so that the parietal bones were flattened. Both these abnormal outlines largely disappeared before the child died. Its weight at birth was three pounds, four ounces.

It is interesting to note the peculiar arrangement of the circulation in the placenta. While attached on its base to a considerable surface of peritoneum, it did not draw its vascular supply from this surface, but from several vessels of from one-sixteenth to one-eighth of an inch caliber, which came from the Fallopian tube, and from a thick band of adventitious tissue, the origin of which, I think, was also from the left tube. Instead, therefore, of the chorionic villi, which were destined to form placenta at the site of the serotina pressing down against the degenerating decidua, that they might spread out over a broad base, as in a normal intrauterine development, and from which they might gain an extensive maternal surface for contact with the maternal blood, they were fed in this case by the direct entrance of large vessels into their villous ramifications. I think it can be safely said that the placenta, aside from the vessels entering the chorion, was entirely fetal in structure, which is a condition not ordinarily occurring in even tubo-abdominal pregnancy. By reason of this fact, namely, that the vascular supply arose from a few vessels, instead of from a general vascularized surface, the ordinary grave difficulty in abdominal pregnancy of removing the placenta without dangerous hemorrhage did not prevail. Even the ordinary firmness of adhesion did not exist; the placenta was easily separated, with the exception of some strong bands of adventitious tissue, the peritoneum being left therefore in a favorable condition for recovery.

PHOTOGRAPH AND SKIAGRAPH OF A GOUTY HAND.[1]

BY A. L. FISK, M.D.,
OF NEW YORK.

R. F., male, aged forty-six, was referred to my class in surgery from the medical class at the New York Hospital in December last, to obtain, if possible, some surgical relief. He is a natural born American, as were both his parents. For many years his father suffered exceedingly with rheumatism. The man's occupation, so long as it was possible for him to follow it, was that of peddling oil from a wagon throughout the rural districts. He has always been in the habit of drinking freely of the malt liquors, but never of spirits. His first attack of gout was during the winter of 1876–77, in the great toe of the left foot; later in the same season a second attack occurred in the great toe of the right foot. Three years afterward, in 1880, both knees were affected; and, in the autumn of 1882, both wrists and hands were the seat of the disease. This attack was so severe that he was confined to his bed for four months. The gouty deposits in the hands appeared first in the left, which now is completely crippled, the fingers being bound down in the palm. The photograph and skiagraph, which were taken early in February last, show the condition of the right hand. The skiagraph demonstrates the fact, most perfectly, that the deposit of salts has occurred entirely in the tissues surrounding the bones and the joints, and not in them. This furnishes a means of differential diagnosis between gout and arthritis deformans.

MEDICAL PROGRESS.

Operation in Lumbar Fractures.—ENDERLEN (*Deut. Zeitschr. für Chir.*, Bd. xliii, p. 329) treated a case of fracture of the sixth dorsal and first lumbar vertebræ with anesthesia and paralysis of the sphincter. Six months after the accident the patient died of phthisis. Transverse sections of various parts of the column revealed slight damage to the fifth and sixth dorsal vertebræ, as well as a considerable fracture of the first lumbar vertebra, the body of which had penetrated the spinal cord to the depth of four millimeters. The microscopic examination of the cord in this situation revealed an almost complete transverse injury, and above this an ascending degeneration.

Making use of this case in connection with the many cases of fracture of the spinal column in the lumbar region, recorded in medical literature, the author does not favor operative interference unless there is present a comminuted fracture or complicated fracture of the arch of the vertebræ, or where there is evidence of the penetration of the bone-fragments. Where these complications are not present it is an extremely difficult matter to make a differential diagnosis between simple concussion and trauma. In both instances early operation is contraindicated. Not even for the evacuation of a blood clot exerting pressure on the cord is an operation advisable. Experience proves that even after the lapse of three months from the reception of an injury an almost complete rehabilitation is by no means a rarity. In one case recovery has been established even after the considerable lapse of 2½ years. In cases where operation has been followed by good results, it remains doubtful whether the merit is due to the operation or the *vis medicatrix naturæ.*

---

[1] Read before the Harvard Med. Soc. of New York, March 27, 1897.

The cord can tolerate a certain degree of pressure, but there are also authentic cases in which, after removal of callus masses and fragments of bone, to the pressure of which the cord has been a long time subjected, recovery has resulted. Even in these latter cases early operative interference is not advisable and three weeks, at least, should be allowed to elapse before resorting to surgical measures. As regards the seat of fracture, numerous autopsies establish that the body of the vertebra is the seat of injury in ninety-five per cent. of the cases. Of the cases operated on, fractures of the arch have been found to exist almost as frequently as those of the body of the vertebra, from which the writer concludes that fractures of the body are always to be considered as of serious import, while fractures of the arch offer more tangible points of vantage to successful surgical manipulation.

The Cause of Death after Extensive Burns.—AJELLO and PARASCANDOLO (*Gazz. degli ospedali e delle clin.*, 1896, No. 83) conclude after elaborate investigations that the cause of death after burns is a toxic ptomain, and is not due to the toxins which may be produced in the burn by bacteria, nor to anatomic changes which the blood-corpuscles or the organs of the burned area may have undergone. They found that if the same portions of the body be excised and then burned that the injections of the fluids derived from them killed healthy animals, with the same symptoms as were exhibited by animals dying from the effects of their own burns. If the burned portions of an animal were quickly removed it exhibited none of the specific symptoms of burning and death therefrom. These symptoms were also avoided by thorough blood-letting, followed by immediate transfusion of healthy blood or artificial serum.

The Fate of Epithelial Masses Experimentally Introduced into the Circulation.—During the Congress of Italian Surgeons held in Rome in October last, SGAMBATI (*Centralbl. für Chirurgie*, No. 51, 1896) read a paper on this subject. Proceeding on the supposition that metastases in carcinoma are developed from little masses of the tumor carried along in the blood or lymph circulation, he attempted to reproduce these symptoms artificially, in order to see whether normal epithelium would lodge and grow in the same way as the abnormal cancer cells. For this purpose he selected the submaxilary gland and the testicle of dogs, preserved the integrity of their epithelium in a warm normal salt solution, and introduced little masses of the tissue into the veins of dogs. After a certain time the dogs were killed and the hemorrhagic infarcts in their lungs were examined microscopically. In most cases the embolic tissues were found to be more or less degenerated. In a single case, in which the dog was killed on the fourteenth day, there was a multiplication of the testicular epithelium which formed the embolus, presenting the appearance of a tubular adenoma. The thrombus in which it lay only partially obstructed the vessel lumen, and to this favorable situation the author was inclined to attribute the cell-growth. In the case of ordinary cancerous metastases, where only a few cells are swept away at a time, the nutritive conditions would be equally or even more favorable.

Limitation of Rotation after Fracture of the Forearm.—From a study of eighty-two cases of fracture of the forearm MINTZ (*Centralbl. für Chirurgie*, No. 52, 1896) concludes that resulting limitation of rotation may be due to: 1. Changes in the soft parts (ligamentous or muscular). 2. Changes in the bone. The latter are of three kinds:

(*a*) Hypertrophic callous. (1) Union between radius and ulna. (2) Pseudarthrosis. (3) Lateral splinters of bone or masses of callous. (*b*) Excessive callous with dislocation of fracture ends. (*c*) Dislocation of fracture ends. (1) Exogenous form of dislocation described by Volkmann, and consisting in the bending of the radius over the ulna. (2) Endogenous, a form of dislocation described by Schmidt, and consisting in the union of the lower radius fragment in the position of pronation or the opposite.

The author makes clear the fact that fractures of the forearm must be individually studied, and not all treated alike according to a preconceived idea.

The Cause of Warts.—SCHAAL (*Arch. f. Dermatol. und Syph.*, xxv, p. 207) saw a wart develop on his own finger in eight days, at a point where a number of minute glass splinters had entered the skin, but without producing any apparent wound. The wart was treated with caustic alkali and removed entire, and the splinters of glass were found in its base. The author raises the question whether all warts do not have a similar etiology. They occur usually on exposed portions of the body and especially in children whose tender skin, and their disposition to play in the sand and dirt, give abundant opportunity for the local irritation of the papillæ by foreign bodies.

The Surgical Treatment of Perforating Typhoid Ulcer.—FINNEY (*Annals of Surgery*, March, 1897), from a study of fifty-two cases of perforating typhoid ulcer treated by operation (six of these are now reported for the first time), finds that:

1. Of all the so-called diagnostic signs most reliance is to be placed upon the development of a severe attack of abdominal pain coupled with nausea and vomiting, and a marked increase in the number of white blood-corpuscles.

2. The surgical is the only rational treatment of perforating typhoid ulcer.

3. There is no contraindication to the operation, surgically speaking, save a moribund condition of the patient.

In performing this operation three things are to be done: First, to find and close the perforation; second, to empty and cleanse the peritoneal cavity; third, to effect and maintain a thorough drainage. The most satisfactory operation is performed as follows: An oblique incision six inches long is made in the right iliac region. The cecum, which is always to be recognized by its longitudinal bands, is the guide to the ileum. From it as the starting point the coils of ileum are systematically drawn out through the abdominal wound, while one assistant wipes the intestine as it is withdrawn with gauze wrung out of a hot salt solution, and another assistant keeps it warm by means of hot towels. All of the affected intestine, even to the duodenum if necessary, should be thus treated. The whole of the peritoneal cavity should then be wiped systematically with gauze wrung out of hot salt solution, attention being directed especially to the pelvic region. Usually irrigation is unnecessary, but the intestines before they are replaced should be thoroughly irrigated and wiped dry. The worst coils should be last replaced and the sutured portion left next to the abdominal wound. Bismuth gauze should be packed around this coil and introduced into the pelvis if necessary. By this means good drainage is insured and escape of feces is provided for in case of extravasation. The abdominal wound should be tightly closed except where the drains escape, and if distension follows operation the bowels should be moved early and thoroughly by calomel in broken doses, followed by salts, and, if necessary, a high turpentine and soap-suds enema. If stimulation is necessary, more reliance is to be placed on hypodermics of strychnin, enemata of several ounces of hot, black coffee, and the transfusion into the cellular tissues under the breast of a quart or more of the normal salt solution, than on any other remedies.

A Clinical Report of the Chemical Examination of Two Hundred Cases of Human Breast-Milk.—ADRIANCE reached the following conclusions (*Archiv. of Pediatrics*, February, 1897), by an interesting series of experiments: Excessive fats are due to an excess of albuminous food, which causes vomiting, diarrhea, and loss of weight, or failure to gain at the proper rate. It may be treated by limiting the amount of nitrogenous elements in the mother's diet. Excessive proteids are due to lack of exercise. This is especially liable to occur in nervous women. It is shown by vomiting, diarrhea, with yellow or green stools, containing curds, and loss in weight, or failure to gain. By regulating the exercise of the mother the elements of the milk can be brought to the normal proportions with a consequent disappearance of the gastro-intestinal symptoms.

During the colostrum period the proteids are very apt to be in excess. This, however, usually passes off in a few days, and seldom requires treatment. Should it persist, it is best to pump the milk, and dilute it with water; or, if this be impracticable, to have a wet-nurse for the child. The influence of prematuracy is well marked; the proteids are much exaggerated, and extend over a longer period than in ordinary colostrum milk. Deterioration of human milk is marked by a reduction in the proteids and total solids, or in the proteids alone. This takes place normally in the latter months of lactation. If it occurs earlier it may be the forerunner of the cessation of lactation, or it may be improved by well-directed treatment. Unless a proper addition is made to the infant's diet, the diminution of proteids will be accompanied by malnutrition and gastro-intestinal symptoms.

Serum Test for Diagnosis of Typhoid Fever.—In the March number of the *Amer. Jour. of the Med. Sciences*, BIGGS and PARK detail the results obtained in experimentation with Widal's serum test in typhoid fever as carried on in the laboratories of the New York Health Deparment. In 108 cases in which, after the completion of the illness, a definite diagnosis of typhoid fever was clinically made, a marked immediate reaction occurred in the first test in seventy per cent. Of the nineteen cases which were examined in the first week, the percentage was nearly as high—namely, sixty-three per cent. The majority of cases which gave no reaction by the fourteenth day failed to give at any time a definite reaction. But in two instances reaction at first appeared at the middle of the fourth week, when the temperature had become nearly normal.

One case was of great interest, as proving that the blood of the typhoid patient may never throughout the whole illness have sufficient agglutinating properties to give a definite reaction in the usual dilution. This case presented the usual symptoms and course of typhoid fever, and by puncture of the spleen typhoid bacilli were obtained.

It was demonstrated that in a certain proportion of cases other than typhoid, there occurs a delayed moderate reaction in a one-to-ten dilution of serum to blood, but very rarely under such circumstances does this reaction occur within fifteen minutes.

It seems probable that a positive diagnosis may be reached in fifty per cent. of cases of typhoid fever and a probable diagnosis in half the remaining cases. While the absence of the reaction for several examinations does not exactly exclude typhoid fever, yet in doubtful epidemics where several cases can be examined the absence of reaction in all of them would clearly indicate that the epidemic was not one of typhoid. For further details the reader is referred to the original article.

THERAPEUTIC NOTE.

Causes and Treatment of Disagreeable Gustatory Sensations.—HERZFELD (*Therapeut. Monatshefte*, Jan., 1897) disputes the commonly accepted opinion that abnormal gustatory sensations are due to digestive disturbances. Aside from those cases due to affections of the teeth, pharanyx, and tonsils, he holds that the crypts in the tonsils often contain masses having a fetid odor. A simple inspection may not suffice to reveal these masses, as they may be situated behind the anterior pillar. With an instrument similar to a crochet hook their presence is easily demonstrated, and the crypts may be slit up in order to prevent a recurrence of the trouble. In other cases the source of the bad taste lies in the posterior nasal cavity, where sometimes a pouch (*bursa pharyngea*) secretes a mucopurulent liquid. In such cases a slight operation will cure the bad taste. Nasal affections, affections of the antrum of Highmore, etc., are further responsible for some of these cases. The author warns against a too hasty conclusion that because of disturbed gustatory sensations the stomach is necessarily at fault.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, APRIL 17, 1897.

AN EPOCH IN MEDICAL EDUCATION IN NEW YORK.

THE announcement was recently made to the medical world that the University Medical School had legally become the Medical Department of the New York University, and had passed over all its goods and chattels and their unrestricted control to the safekeeping of the authorities of the University. Following closely upon the heels of this intelligence comes the statement that Bellevue Hospital Medical College, in response to an invitation from the University, has done the same thing. Hereafter these two friendly rivals will nestle in the bosom of a common *alma mater*, will be consolidated into one institution, and be known as the New York University Bellevue Hospital Medical College.

The students and alumni of the former institutions, which now pass out of existence, are expected to embrace each other as brothers, accept their foster mother, and be enrolled and known as alumni of the New York University. During the present year the combined enrollment of the two schools has numbered 1057 students, while the combined alumni number 11,434. There are 116 members of the two faculties. In the new arrangement they place themselves entirely under the direction of the University Council, and rely upon that body for their future selection and compensation. It is rumored that they will all place their resignations in the hands of the Council, leaving that body untrammeled in its selection of a faculty.

In this consolidation the University acquires ownership of all the property, rights, leases, and privileges of both institutions, and assumes all their obligations. The terms of the transfer are absolutely without condition.

It is impossible to estimate the importance of this action, or to conceive of the boundless possibilities it has in store for the advancement of medical education in New York City. By this arrangement there will be secured a faculty composed of two bodies of professional men, each one of which has been amply sufficient for the teaching requirements of a successful and prosperous school.

The financing of a medical school is a source of anxiety, or, at least, of constant care. The professors will now be relieved of this responsibility, and their only concern will be to see that they are provided with proper teaching facilities. This will add vastly to the *esprit de corps*, and the large number of teachers will permit of more individual, personal work. An opportunity is now afforded to banish forever the old system of didactic lectures, and introduce methods of instruction along more modern and improved lines. The duty of a college professor is no longer considered fulfilled when he has monotonously and automatically gone over a subject in the presence of three or four hundred drowsy, listless, inattentive students. The successful teacher is the one who throws such a charm about a subject as to arouse the interest and ambition of the student to pursue investigations on his own account, and then places within his hands instruments of precision, and provides methods of investigation which shall enable him to work out for himself the ultimate finalities of the subject. To educate is to draw out latent powers, not to fill up empty reservoirs.

In this unification of forces the lecture halls and work rooms will doubtless be ample for all requirements. The Loomis and Carnegie laboratories are already well equipped, and offer facilities for the most thorough training. The hospital advantages are great; the buildings are conveniently located;

and the clinical material sufficient to meet all demands.

Last, but not least, the combined alumni of these two institutions, numbering as they do over eleven thousand active physicians, scattered all over this broad land, will watch with jealous eye the progress and success of their *alma mater*, and constitute a strong arm of support. It has been for some time apparent that medical education in America has reached a point where it needs endowments to carry on the work, in accordance with the demands of modern medical requirements. Since the proprietary element is now eradicated from the University Bellevue Hospital College, it is the expectation that gifts will flow into the treasury of the New York University for the aid of its medical department. The advantages already offered, and those which will be offered in the immediate future, will tend more strongly than ever to attract students to this center of medical instruction.

The four-years' course is already established. To make this additional time profitable to the student, it must be spent in carefully directed investigations in hospital, laboratory, and clinic. These practical facilities can now be more fully than ever provided in this great medical institution of New York.

AGAIN, THE INDECENT ADVERTISEMENT.

The boy who is bad but not irretrievably wicked, will avoid the person whom he has insulted or injured, if not from cowardice, at least from a sense of shame at meeting face to face one to whom he owes an apology. We have often wished that the quack would show something of the same delicacy and would not have his advertisements bestowed upon his decent professional cousins as impartially as upon the laity whom he seeks to victimize. Yet,so far as we can judge, our doorsteps are as freely supplied with information regarding the folly of youth and the means of rejuvenation, with the hints as to how to save doctors' bills, and with the advertisement of the monthly regulator and the ladies' syringe, as any of our neighbors'. We note particularly a recent menstruation circular, which shuns the prevalent idea of internal medication as irrational, and tells how the monthly flow may be reestablished by means of injections, using, of course, a particular brand of medicated tablets. We agree in most respects with the opinions of the advertiser, especially with the conspicuous notice that such injections are very likely to produce miscarriage in case the "lady" should happen to be pregnant. Such a complication would, of course, lead the aforesaid "lady" to omit the use of a syringe. We have all noticed in practice how many girls and married women consult us because of irregular menstruation due to constitutional causes, or to getting the feet wet, or to some nervous reflex, and have often observed the rarity with which supposedly pregnant women apply for the restoration of menstruation. Therefore, we are able to appreciate the number of cases of innocent amenorrhea which our advertising cousin will relieve and, in our mind's eye, can see the young matron making an unerring diagnosis of pregnancy in the early weeks and accordingly putting away her "boon to women" until pregnancy and lactation shall have been passed. But this sort of advertising will continue until the laity will appreciate the magnitude of its evil results and support the medical profession in the attempt to bring it within legal control. We would even go so far as to suggest that the good ladies who are endeavoring to raise the age of consent till a woman has gray hairs, would find a more practical, if not an ethically superior matter for their consideration, in the indecent pamphlets and suggestive newspaper advertisements of quacks.

In this connection, we take the liberty to criticise the advertisement of a physician who is not a quack but a professional man in the best standing before the law, who is widely known as a benefactor of the race, and who is a pillar of the church which he attends. We notice this man's advertisement of a third of a column in our daily paper. At the head of the advertisement is a cut representing the angel of death fleeing from an open door, in which stands a woman pointing to a crucifix between the panels. The text alludes to the "Biblical story of the passover," and draws the moral that "The chosen people are the healthy people. Nine-tenths of the deaths among children are due to the ill-health of the mothers during the period preceding motherhood." Or, perhaps it would be more correct to say that the real moral is that women should buy the doctor's medicine "at any drug store," and should also get his book, containing plain talks on all sorts of ailments, made plainer by illustrations.

What adequate comment can be made on such a case? Here is a man whose status as a physician, as a member of society, as a support of his church, is equal to that of any reader of these words. He lives in an age when the tolerance of persons with deep religious convictions ought to be equaled by the respect shown by those who lack these convictions, for the objects and writings which the former venerate. Yet he uses the sacred writings of Jew and Christian to draw dollars to his safe, an enlightened community reads his advertisement with equanimity, a liberal church accepts his offering, and only a jealous medical profession, following antiquated precedents, is stirred to feeble protest.

ECHOES AND NEWS.

Anti-spitting Ordinances.—Rochester, N. Y., and Columbus, Ohio, have passed ordinances prohibiting expectoration in public conveyances.

Nurses to Start for Crete.—Mrs. Ormiston Chant, the social reformer, and six nurses, started from London, April 8th, for the Island of Crete.

Appointment.—Dr. Robert Abbé has been appointed to the newly created position of assistant surgeon to Roosevelt Hospital, with a seat in the Medical Board.

Contagion Conveyed by Letter.—A case of scarlet fever in the town of Clinton, Me., is believed to have originated from a letter written by a relative of the sick man in the West who had been suffering from the disease.

Medical Requirements.—An amendment to the Nebraska medical practice act, adopted by the Nebraska State Senate, requires a four-years' attendance at a medical college before a license can be granted. The present law requires three-years' attendance.

Experimental Tuberculosis in Chickens.—Mafucci has shown experimentally that tubercle bacilli inoculated into hen's eggs before incubation remained quiescent during the period of embryonic development, but caused the death of most of the chicks from tuberculosis in three weeks to 4½ months after birth.

The New York City School Inspection.—In the report for the first week of five school days of the medical inspection of schools, conducted under the direction of Dr. A. Blauvelt, the total number of children examined was 13,176. The number excluded in all was 569; 481 from the public schools, 88 from the parochial schools.

Increase of Insanity in England.—The report of the Commissioners of Lunacy to the Lord Chancellor, on insanity in England and Wales, has just been issued in England. The figures given by the commissioners show that the numbers of reported lunatics increased from 36,762 in 1859 to 96,446 in 1896, and the ratio from 18.67 to 31.38 per 10,000.

Why Fashions in Surgery Change.—Lawson Tait says that the only way an operation can be estimated justly is to ascertain its remote results. "It would matter very little if an operation had no primary mortality at all if it left the majority of its subjects maimed, halt, or insane, at the end of two years. The absence of injury in secondary results is the cause of so much change of fashion in surgery, to say nothing of medicine."

The Excursion to Moscow.—At the suggestion of the American Committee of the International Medical Congress a special tour to Moscow has been planned under the supervision of Messrs. Thos. Cook & Son. The party will leave New York July 3d, and will be divided in such a way as to enable any member of it to choose one of three itineraries, each one embracing a very satisfactory tour of Europe. A considerable reduction in ordinary rates will be secured by this arrangement.

A Municipal Laboratory for New York City.—A bill has been introduced in the State Legislature providing for a municipal laboratory in New York city, the directors to be appointed by the mayor, one to be a graduate in medicine and an expert in chemistry, and one in bacteriology; salaries to be not less than $8000, nor more than $15,000. There may be an assistant in each department at a salary of $2500. All investigations desired by the Coroners or the District Attorney shall be made free of charge.

Brooklyn Water Supply.—Health Commissioner Emory of Brooklyn has submitted to Mayor Wurster a report showing in detail the filthy condition of the sources of Brooklyn's water supply. The commissioner sounds a warning to the city authorities, and tells them that with the experience of last summer fresh in mind, they cannot afford to disregard the admonitions received from the biological and chemical experts. These, briefly, have shown that at five or more places along the watershed it is common to find bacteria which point to sewage inflow.

Speers Memorial Hospital at Dayton, Ky.—The Speers Memorial Hospital in Dayton, Ky., a city of about eight thousand inhabitants, is rapidly nearing completion, and will be one of the best-equipped institutions of the kind in the West. This institution was founded in July, 1895, by means of a fund bequeathed by the late Mrs. Elizabeth Speers, who died May 13, 1894. The fund aggregated about $100,000. The building has thirty-two rooms besides the public wards, of which there are four, two in each wing, capable of accommodating twelve patients.

Mortality in the French Navy.—At the Paris Academy of Medicine MM. Vincent and Burot recently presented some statistics of mortality in the French navy. For the five years 1891–95 out of 198,313 men there were 2253 deaths, or 11 per 1000. Tuberculosis was responsible for a quarter of this mortality, and was found to be more frequent in the navy than in the army. Malaria, dysentery, and cholera also showed a heavy death-rate, and so did accidental deaths and drowning. The mortality among the medical officers and dispensers was 19 per 1000.

Death of a Medical Centenarian.—Dr. De Bossy, of Havre, France, died there on March 24th. He was born in Paris during the Reign of Terror, April 9, 1793, and had reached the age of 104 years. He received his early education and began his medical studies in England, but finally settled in Havre, where he continued to climb steep stairs to sick rooms and minister to his patients after he had passed his century of years. He said of himself that he had throughout his life used everything, but abused nothing. Dr. De Bossy's father lived to the age of 108.

Obituary.—Dr. Charles Stammer, one of the leading physicians of Schenectady, N. Y., and a prominent member of the American Medical Association, died April 7th, aged sixty-five years. Death was due to apoplexy.—Dr. J. H. Walton, a well-known physician of Dubuque, Iowa, committed suicide in Lincoln Park, Chicago, April 4th. He was walking along one of the driveways with a friend, when suddenly he drew a razor from his pocket and cut his throat, dying in a few minutes. No reasonable cause can be assigned for the act.—Dr. Morvan died recently in France, aged seventy-three years. He was the first to describe the group of clinical symptoms known as Morvan's disease, which he considered a form of syringomyelia.

Things not Always What They Seem.—From Detroit comes a story which we hope is true about an efficient but illiterate domestic servant who was brought into serious, but happily not fatal, danger by her undue confidence in the deductive system of reasoning. The woman suffered from rheumatism, and one rainy day last week, when her aches were especially severe, she came across a bottle labeled with a few written words and a print of skull and crossbones. Immediately she reasoned that the bottle contained a medicine for complaining bones, and she proceeded to take a heroic dose of its contents. Two doctors and a stomach pump saved the woman's life, but she no longer sees unity of design in the universe and her trust in logic is gone forever.—*N. Y. Times.*

God and the Microbes.—A fairy story written by an authoress of the tender age of six years has just appeared on the shelves of the book venders. The little fairies therein depicted in due time become ill and require the services of a physician. When the fairy doctor arrives he discovers that one has scarlet fever, another diphtheria, and a third typhoid fever. He tells the fairy godmother all about microbes and germs, and instructs her to boil the water. The fairy godmother says she does not understand; if the germ has the fever, why doesn't the fever, which kills little boys and girls, kill the germ? And if the germ doesn't have the fever, how can it give the fever? How can a thing give a thing it doesn't have? The fairy doctor says, "Nobody knows but God."

Kissing the Book.—Acting under orders from the authorities of the town of Bradford, England, a chemist has just made an examination of a Testament which has been used in the Ripon court for sixty years, and which is said to have been kissed by 40,000 people. The analysis was made with a view to ascertaining what danger there is in the practice of "kissing the book." No germs of typhoid fever, tuberculosis, or diphtheria were found. The chemist identified seven species of micro-organisms which cover the three divisions of the fungi order. The only germ of a dubious character was one which is usually found on wounded and diseased skin. Although this germ is not necessarily harmful, there are conditions in which it might produce unpleasant complications, and the chemist said he would not kiss any surface upon which they were spread.

Prosecution for Practising Medicine Without a License.—A curious little problem in law and ethics came up for solution recently at Hazleton, Pa. A man was arrested there for practising medicine without having been registered, as the law of Pennsylvania and most other States requires. He confessed his guilt and admitted that he was well acquainted with, and approved of, the regulation he had violated. Then he proceeded to assert, and to prove by documentary evidence, that he had been graduated from the Medical School of the St. Petersburg University, and had practised in the Russian capital for years. He was therefore quite eligible for registration in this country, but on reaching Hazleton he had found himself penniless and without friends. After he, his wife, and his three children had gone hungry for several days he determined to risk imprisonment in order to supply the wants of his family and incidentally to earn enough money to pay the register's fee. Immediate denunciation and arrest followed. Investigation showed that the man's story was true in every particular. His wants were supplied and he is now openly and successfully following the profession, the practice of which had made him a technical criminal.—*N. Y. Times.*

Special Exercises at the Jubilee Meeting of the American Medical Association.—The Committee of Arrangements has set aside an hour on the second day of the meeting for exercises to commemorate the founding of the Association in Philadelphia in 1847. Dr. Davis, who is recognized by all as the moving spirit in the enterprise, will read a short paper, giving an account of the origin of the Association, and how the objects for which it was founded have been attained. In addition to the address of Dr. Davis there will be two or three other short addresses to add to the interest of the occasion. The founders of the Association believed that it would raise the standard of medical education and combine the medical profession of the United States in one body. The committee has taken steps to secure the attendance at the meeting of the Presidents of the State Medical Societies and the Presidents of the State Boards of Medical Examiners as an illustration of the success attained through the instrumentality of the Association. Of the original members of the Association there are still living Dr. N. S. Davis, of Chicago; Dr. Alfred Stillé, of Philadelphia; Dr. John B. Johnson, of St. Louis; and Dr. David F. Atwater, of Springfield, Mass.

The committee hopes that these gentlemen will all be present to take part in the meeting.

Commissions for the Doctor.—A subscriber of the NEWS has sent us the following circular which he received recently, and which, he significantly remarks, speaks for itself:

"Philadelphia Optical Company, registered, Manufacturing Opticians, 87 King street East, Toronto.

DEAR SIR: If you have not been writing prescriptions for spectacles we would like to have you begin. You can do much good by doing so, and it will be profitable to you. All you need to do is to write the patient's name on the blank we send you, and we will give you . . . of what the patient pays us for the glasses. We have added to our store our own grinding machinery, and can now grind to order any glass for any complicated case in a few minutes. In the past the writing of doctors' prescriptions has been confined to eye specialists. We have in our house an expert optician graduate in optics who tests each eye with the Javal Opthalmometer (*sic*) and the Opthalmoscope (*sic*). If you send your patients to us we will benefit them with glasses at a reasonable price, and give you . . . of what they pay us. This will be all clear profit to you. And you get credit of prescription. We have everything in spectacles in stock, from the cheapest to the best. Hoping you will give us a trial, we remain, Yours truly."

CORRESPONDENCE.

A BOOK REVIEW CRITICISED.

To the Editor of the MEDICAL NEWS.

DEAR SIR: In glancing over the pages of your journal of January 16, 1897, my attention was called to the review of Dr. McGillicudy's book on "Functional Nervous Diseases in Women." Your reviewer so completely condemned the book from every standpoint that my curiosity was aroused and I determined to read it and judge of its merits for myself. Its perusal has led me to feel that your reviewer has either not read the book, with the modest claims made in its preface, or else his condemnatory utterances result from inability to appreciate its good features, or from personal prejudice.

His first criticism would seem to be answered by the fact that there has been no similar publication in the English language.

His second criticism—that much of what the book contains "has appeared over and over again in medical journals, and in monographs and text-books on general nervous and gynecological diseases"—seems to me to be commendatory rather than derogatory, inasmuch as such a compilation gathers much widely scattered material, together with the author's own personal investigations into one compact volume.

As to its typography and chromolithographs, the standing of the publishers will answer for that.

Yours truly,
WENDELL C. PHILLIPS.

NEW YORK, March 10, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

PENNSYLVANIA HOSPITAL'S NEW CLINICAL AMPHITHEATER—ACADEMY OF SURGERY—COLLEGE OF PHYSICIANS—PATHOLOGICAL SOCIETY—DR. H. A. KELLY—DR. J. W. WALK—DEATH OF DR. ENGEL—THE D. HAYES AGNEW MEMORIAL PAVILION—DR. LUDWIG HEKTOEN—CITY BACTERIOLOGICAL LABORATORY.

PHILADELPHIA, April 10, 1897.

WITH the opening of the new clinical amphitheater and receiving wards of the Pennsylvania Hospital a notable addition to Philadelphia's hospitals has been made. The amphitheater, constructed of tile, marble, and iron, and erected upon a steel substructure, occupies a large part of the new building, and is thoroughly equipped with every modern appliance for insuring surgical asepsis; it will seat several hundred students, and is admirably adapted for the purposes for which it is intended. In addition to men's and women's receiving wards, isolating rooms, and a number of small operating rooms, elaborate sterilizing and filtering plants are contained in the new building. The first public clinic was held there on April 3d.

The last monthly meeting of the Philadelphia Academy of Surgery, held on April 5th, was devoted to the consideration of tetanus antitoxin. "A Case of Traumatic Tetanus in which Antitoxin was Used" was reported by Dr. W. G. Porter. Dr. C. B. Penrose read a paper on "Tetanus following Trachelorrhaphy and Perineorrhaphy in which Antitoxin was used without Success." Dr. T. S. K. Morton reported a "Case of Tetanus Treated by Antitoxin as well as by Blood-letting and Saline Infusion." Dr. W. J. Taylor mentioned a case of tetanus occurring in his practice, in which he had administered antitoxin, and although the case did not terminate fatally, Dr. Taylor was inclined to think that it was one in which the patient would have recovered without the use of the remedy. From the discussion of the papers it was apparent that tetanus antitoxin has not yet been established on a firm therapeutic basis.

A stated meeting of the College of Physicians was held on April 3d, at which many valuable papers were read and discussed. One presented by Dr. J. B. Deaver on "Some Mooted Points in the Pathology of Appendicitis, with Especial Reference to the Condition known as Appendicitis Obliterans," provoked considerable discussion, and proved a rare addition to our knowledge of this form of the disease. In the single instance of obliterative appendicitis out of over forty cases of other forms of the disease upon which Dr. Deaver had operated during the last three months, the appendix was converted into a fibrous cord; in the other cases there was a contraction of the lumen of the appendix on the proximal side. In the discussion of this paper Dr. Hearn said that every case of appendicitis which he had seen had been preceded by some error in diet, with which Dr. Harte, who also discussed the paper, agreed. Dr. C. K. Mills facetiously remarked that from the education of the laity generally, and from the tendency of certain neurotics to exaggerate and to imagine ills, some cases might almost be called "cerebral appendicitis."

Dr. H. A. Hare, in a paper dealing with "The Rapidity of the Elimination of Drugs and its Influence upon Their Administration," discussed the inconsistency of giving, as is often done, three or four daily doses of a drug like prussic acid, which is very rapidly absorbed and eliminated; and of administering in rapidly succeeding doses drugs like digitalis and the bromids, whose assimilation and elimination is slow. Dr. Hare concluded that drugs should be administered in doses sufficient to produce the effect sought for, and that this condition should be maintained by smaller doses at intervals depending upon the rapidity with which the drug in question was eliminated. Other papers at this meeting were read by Drs. F. A. Packard, J. Dutton Steele, Arthur Van Harlingen, and J. B. Roberts.

At a meeting of the Philadelphia Pathological Society, held on April 8th, Dr. D. L. Edsall reported an instance of an unusually large gumma of the kidney, and exhibited the specimen from the case. Dr. Edsall and Dr. T. S. Westcott read a paper on "Tuberculous Pericarditis." Dr. M. H. Fussel discussed "Gangrene of the Lung," and reported "A Case of Hemorrhagic Purpura." An instance of cerebral hemorrhage occurring in a girl nineteen years old was quoted by Dr. J. P. Tunis.

Dr. H. A. Kelly, of Johns Hopkins University, delivered a lecture by invitation on "Eras in Gynecology" at the Medico-Chirurgical Hospital, on the evening of April 3d. At the conclusion of Dr. Kelly's address he was tendered a reception by Dr. W. E. Ashton, at which the faculty of the Medico-Chirurgical College and many prominent Philadelphia medical men were present.

Dr. James W. Walk has been appointed by the Mayor a member of the Board of Health to fill the vacancy caused by the death of Dr. P. D. Keyser. Dr. Walk resigned from the Board of Charities and Correction in order to accept this position.

Dr. Hugo Engel died suddenly of pneumonia on April 5th, at the age of fifty-two years. Dr. Engel was formerly connected with the teaching staff of the Jefferson Medical College, of which he was an alumnus, and at one time occupied the chair of nervous diseases at the Medico-Chirurgical College.

For equipping and furnishing the new D. Hayes Agnew Memorial Pavilion of the University Hospital the State Legislature has been asked to give $90,000, and for maintenance an appropriation of $50,000 annually for two years is sought for. By the opening of this new wing 160 additional beds are added to the hospital.

A reception is to be tendered Dr. Ludwig Hektoen, of Rush Medical College, Chicago, on April 22d by the Philadelphia Pathological Society. Dr. Hektoen is to deliver an address before the Society on "The Lesions of the Intercellular Substance of the Myocardium," on the same evening.

During the past year 2385 cultures from cases showing evidences of diphtheria were made at the City Bacteriological Laboratory, with the result that 1442 cases were diagnosticated as true instances of the disease. An indication of the increasing confidence of practising physicians in the laboratory diagnosis of diphtheria is shown by the fact that seventy-six per cent. of the cases examined last year were classed as "doubtful" by the attending physician, while the preceding year a clinical uncertainty was expressed in but forty-one per cent. of the total cases sent to the laboratory. A total of nearly six thousand cultures, both primary and secondary, were examined last year.

OUR ROME LETTER.

[From our Special Correspondent.]

THE STRIKE OF THE STUDENTS AT THE ITALIAN UNIVERSITIES—THE NEW ROMAN POLYCLINIC—DURANTE'S WORK IN INTESTINAL ANASTOMOSIS.

Rome, March 10, 1897.

The Italian Universities are just now confronted by a state of affairs that is extremely interesting to a foreigner. There is a strike (acioppero, as they call it here) among the students of all the universities of the kingdom, and for the moment higher education is at a standstill. There is a solidarity in the student-body here that Americans with their sometimes more than friendly rivalry between universities would find it hard to understand. Such strikes have occurred before, but usually have not amounted to much, though for awhile they may have stopped the teaching at several, or even at all, of the institutions. This year the new Minister of Education, Gianturco, attempted the introduction of some reforms in university matters, and, among other things, he decreed that a supplementary examination should take place about the middle of each scholastic year. His earlier reforms had caused a good deal of disaffection, and this last step at once met with open resistance. The students, first at Palermo, and then gradually at the other universities, refused to continue their studies unless the minister's decree was rescinded. This demand was refused on the part of the government, and an attempt was made to pick out and properly punish the ringleaders in the movement, but without result. This all happened about the beginning of February, and no classes have been held since that time because there has been no one to attend them. The reopening of the university here in Rome was announced for Thursday, March 4th, the day after the termination of the carnival, but as it was realized that it would prove a fiasco, and as the present government, in the disaffected condition of political affairs, cannot afford to be made rediculous, the reopening was postponed indefinitely.

It looks very much as though the current college year was going to be lost to all classes of students as so much of it has been wasted in the squabble. The medical students have usually been most prominent in the student strikes but this year they seem to have followed only where others led. The prospect of the loss of a year's work should apparently bring the men to their senses, but the spirit of disaffection toward the present government is so profound that the sacrifice does not seem to them to be too great. Meantime the students are organizing political schemes for the overthrow of the present ministry at the approaching elections, and are making public demonstrations in the different cities in favor of Candia. These are partly and supposably manifestations of good will toward this candidate, but are also thinly veiled evidences of the present restless condition of the Italians themselves, and so have been forbidden in some places. Our independent American system of university education may have its disadvantages, but at least it is not open to the serious drawbacks that are thus laid bare in a too paternal system of State education.

On the other hand, one of the benefits of State-directed medical education is the magnificent new hospital, "the Polyclinic," for teaching purposes, which is just about ready for occupation. It is beautifully situated on some high ground, just outside the Porta Pia, to the right and beyond the walls of the old Roman "Castra Pretoria." It is an immense building, the hospital departments proper or wards being two stories in heighth, and ten in number in front, branching off from a corridor that runs on each side of the main central building, which is to be more especially devoted to teaching and administration purposes. One half is to be devoted to clinical medicine, and the other half to clinical surgery. It covers an area of ground corresponding to the Pretorian camp in size, and is to have accommodations for about 1000 patients. It is distinctly modern in every respect; the wards are high, well lighted, and airy, and the operating and consulting rooms contain the very latest improvements. No expense has been spared to make it a model hospital for teaching purposes in every respect. Rome has been laboring under the serious disadvantage of her old-fashioned hospitals for a long enough time, and now is to be congratulated on this magnificent addition to her medical equipment.

Things medical are generally very quiet during the enforced vacation. Professor Durante continues his surgical clinics at the Instituto Chirurgico, where his work in intestinal anastomosis has attracted a good deal of attention. He replaces the Murphy button for end-to-end anastomosis by a cylinder of maccaroni that is smaller in diameter at the middle than at either end. In shape and general appearance it resembles the cylinders of decalcified bone, that have been found so suitable for the same purpose in England. His results are excellent and the use of a material that is absorbed *in situ* seems better than a foreign body that must eventually be ejected. The comparative simplicity and inexpensiveness of the cylinder also commends the method.

POST-OPERATIVE ACUTE SUPPURATIVE MENINGITIS CURED BY TREPHINING—OCCURRENCE OF INTESTINAL LITHIASIS—OPERATIVE TREATMENT OF CARCINOMA OF THE RECTUM—EARLY NERVOUS SYMPTOMS OF POTT'S DISEASE—MULTIPLE LYMPHADENOMATA WITHOUT LEUCOCYTHEMIA.

At a session of the Academy of Medicine held March 2d, Berger discussed *a case of acute suppurative meningitis following operation and healed by surgical measures.* The patient was a woman, aged thirty-three, who possessed, from her fourth year, a swelling corresponding to the frontal sinus. Under the supposition that it was a cyst, Luc resected a part of the anterior wall of the frontal sinus, and there escaped spontaneously, and by curetting, a quantity of colloid and fungoid material, the tumor being a sarcoma. The wound suppurated, and one month later it was enlarged, and an intra-orbital prolongation of the tumor was extirpated after resection of the superior wall of the orbit. Despite drainage, symptoms of meningitis and paralysis of the right side appeared on the eighth day. The posterior wall of the sinus was trephined, the dura was incised, and a coating of pus was wiped from the pia, and the wound drained with iodoform gauze. At the close of the operation the patient came out of the coma which had for some time existed, and recovery was ultimately complete, although complicated by an infectious pneumonia.

The case well illustrates the dangers which may follow operations upon the frontal sinuses. Gauze drainage is certainly preferable to suture in these cases. The advantage of early and wide trephining in intracranial suppuration, whether of mastoid origin or occurring elsewhere, is also illustrated by this brief history.

During the session of March 9th, Dieulafoy said that as a result of observations made by himself, and those previously made by Laboulbene, he concludes that *intestinal lithiasis is of frequent occurrence, and is often associated with mucomembranous enterocolitis.* The gravel or sand or genuine calculi are formed chiefly of calcium and magnesium salts. Etiologically, intestinal lithiasis is oftener found in persons of a gouty diathesis, but this rule is by no means invariable. There may be no special symptoms, but usually there is abdominal pain—often a veritable colic—followed by stools containing a greater or less quantity of gravel, either with or without a mucus discharge.

Quenu discussed *the treatment of carcinoma of the rectum* before the Surgical Society, February 24th. The establishment of an artificial anus, even with any amount of irrigation, etc., of the lower bowel, is not sufficient to secure asepsis in a subsequent operation of extirpation. It is indispensable to carefully obliterate both ends of the diseased organ, so as to remove it en masse, like a cyst. And an incision into the cancerous rectum, or a digital exploration of it during operation, is a serious error. Quenu's method is to make an oval incision around the anus from the coccyx to the superficial transversus peronei muscle. The anus is carefully closed. The sphincter on each side of the anus is dissected and then the superficial and deep transversus peronei until the anus is entirely separated from the levator ani. In this manner the prostate is easily reached, and may be resected in whole or in part, provided a catheter be introduced into the urethra to protect this canal from injury. By this method ten or twelve centimeters of the bowel are readily freed and brought down without great traction.

At the session of the Medical Society of the Hospitals held February 26th, Siredey, in speaking of *the early nervous symptoms of Pott's disease,* placed especial emphasis upon exaggeration of the reflexes indicating a special excitability of the spinal cord, and fever, pointing to infection frequently due to tuberculosis.

Achard said that these and other early manifestations were more frequently seen in adults than in children, because of the slow progress of vertebral tuberculosis in adults.

Moutard-Martin emphasized the importance, in all cases of persistent neuralgia, of the careful examination of the bones. He recalled one case in which excruciating sciatic pain existed for over two years before an osteosarcoma of the iliac fossa gave evidence of its presence by the least swelling.

At the session of March 5th, **Hayem** presented a man who, five years previous, was obliged to give up his work on account of a febrile affection, which was diagnosed as mumps. The swelling never entirely subsided. Some time later the neck began to swell, and then the groins, and ultimately the axillæ, accompanied by cyanosis. The swellings were diffuse, ill-defined, soft at some spots and hard at others, corresponding to indurated and hypertrophied glands. Both the red and white blood-corpuscles were increased—the latter slightly so. Iodid of potassium and arsenic were taken without benefit, but thyroid capsules caused the disappearance of the cyanosis and feeling of depression, while the swellings grew softer under this treatment. The disease seemed to be that of *multiple lymphadenomata without leucocythemia*, differing from the ordinary type of the affection by the participation in the process of the periglandular tissues.

At a meeting of March 12th, **Widal** and **Meslay** described a *post-mortem* examination performed by them upon a man who died of staphylococcus pyemia following a suppurative bunion. There were abscesses in the kidney, epididymis, and lung, and about a quart of pus in the pericardium. There was no history of pain in the gastric region, and there had never been any attacks of vomiting or hematemesis. There was, however, a perforating ulcer of the stomach, the base of which was formed directly by the subperitoneal adipose tissue. Numerous sections were made in the ulcer, but no staphylococci were found. Nevertheless, the writers were inclined to ascribe the cause of the ulcer to the staphylococcus infection.

At a meeting of the Biological Society, held February 27, **Gilbert** described *guiacol phosphate* as a crystalin body without color, smell, or taste, soluble in strong alcohol, but insoluble in water, glycerin, or oil. It contains about ninety per cent. of guiacol. It passes through the stomach without change, but is disintegrated in the intestine and absorbed. It is eliminated chiefly by the kidneys. Compared with other compounds of guiacol, the phosphate possesses the advantage of having a larger proportion of this substance than the others, excepting the carbonate and the phosphite. The phosphate and the phosphite are superior to the carbonate, in that their disintegration sets free a phosphoric radical, instead of indifferent, carbonic acid. On account of a higher melting point (97° C.) and its insolubility in oil, the phosphate cannot be applied to the skin or used for interstitial injections, suppositories, or enemata. On the other hand, the absence of taste and smell, its insolubility in the stomach, and its low degree of toxicity are advantages which will secure for it a place in therapeusis.

Vienna.

FATAL HEMORRHAGE FROM THE EAR IN A CHILD—THE SURGICAL TREATMENT OF SPASTIC PARALYSES—TERTIARY MANIFESTION CLOSE UPON THE PRIMARY SORE.

At the session of the Imperio-Royal Society of Physicians held February 26, **Panzer** described *a case of hemorrhage from the ear*, occurring in a child aged two and a half years, who was operated upon some time previous on account of an aural discharge. Without any evident cause there suddenly developed a hemorrhage from the ear, which was imperfectly controlled by tampons. At autopsy the brain was found to contain numerous tubercles, some of them as large as a pigeon's egg. The temporal bone was carious in many places. The process had eaten away a part of the wall of the carotid canal with resulting hemorrhage. This accident has happened, as far as known, only thirteen times in children.

At the session of March 5, **Lorenz** read a paper upon the *surgical treatment of spastic paralyses*. For practical purposes it may be said that the condition in these cases is one of weakened cerebral influence, and the possibility of walking is often entirely abolished by the contractions. Improvement may be hoped for along two lines. In order to accommodate for the loss of power of certain muscles one may employ apparatus, and counteract the excess of power of some muscles by the use of elastic bands. This method of treatment gives no permanent result, for either immediately or soon after the removal of the apparatus its good effects disappear.

Another line of treatment is therefore to be recommended. The case is not one of paralyzed muscles, but, on the contrary, of muscles which are acting in a vehement, though irrational way. The object of treatment is therefore to lessen their power, while increasing the voluntary control over them. At the same time it is desirable to increase the power of the weaker muscles, and in this way to establish an equilibrium between flexors and extensors. The first of these requirements is reached by tenotomy and the separation of the cut ends. Thus in case of a contractile gastrocnemius, etc., producing the deformity called equinus, a division of a tendon and the separation of the cut ends allows the joint to be moved to greater extent than before, while the posterior muscles are prevented by the lengthening of the Achilles tendon from exerting their full force. There follows in the course of time a spontaneous regulation of the relation between muscle and tendon, although there is a continual tendency on the part of the latter to shorten, unless apparatus be worn to prevent this.

In the form of spastic adduction at the hip-joint with knees crossed and walking absolutely impossible, one may, by gradual stretching of accessory muscles, lengthen them, not in the sense that there is any break in the continuity, but rather that the fine muscular bundles give way in numerous places. In recurrent cases, neurectomy is to be advised. Children walk at first with the feet somewhat separated, but the improvement over the previous condition is striking enough. Electrical treatment, massage, and gymnastics serve not only to restore the power of the weakened muscles, but stimulate the cerebral innervation.

Kahame described to the Medical Club, February 24, a case of syphilis in a woman, aged twenty-eight, who, *before the exanthemata appeared, suffered from periostitis of the skull and the clavicle.* She was treated with twenty-nine applications of mercurial ointment. Later there developed rupia syphilitica, headache, dizziness, whirring in the ears, disturbance of sight, and lancinating pains. There was evidently a lesion in the central nervous system, perhaps a meningitis. At the same time there developed a bilateral atrophy of the optic nerve, with Rhomberg symptoms, and increase in the patellar reflex. Cases in which tertiary lesions follow rapidly the initial symptoms of syphilis are not unknown to medical literature. Kahame at one time saw two cases in whom, before six months had elapsed after the primary lesion, hemiplegia developed.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting held March 27, 1897.

The President, John Winters Brannan, M.D., in the Chair.

The paper of the evening, entitled,

"HYDROTHERAPY IN TYPHOID FEVER"

was read by Dr. Frank H. Daniels.

(See page 487)

DISCUSSION.

Dr. R. W. Wilcox said he was glad the author had entitled his paper "Hydrotherapy in Typhoid Fever," because he had never been able to understand why this method of treating typhoid should be called the Brand method. The first important contribution to the subject was that by Currie, and Brand's communication, in 1861, practically attracted no attention until Currie endorsed the treatment in 1866. The Currie-Jürgensen treatment shows many variations in theory. In the beginning, the treatment was used to reduce temperature, but this main reason for its employment seems to have been lost sight of. It was claimed that much good was accomplished by the treatment in the way of stimulating the nervous system, but this is difficult to prove or disprove. The treatment undoubtedly increases the elimination of the urinary toxins, but if this is the main reason for its use in typhoid, it does not seem a sufficient argument. It is generally admitted that the treatment has nothing to do with the patient and nothing to do with the disease. In his experience, the treatment of typhoid by baths had not influenced the course of the disease, except so far as the increased elimination of toxins was concerned. The success which was claimed for the treatment was to be explained by the earnestness and enthusiasm of those who practice it, and by the fact that it gives a direct road in which the physician can travel.

Dr. Arthur L. Fisk said that when he had typhoid himself he had been given the baths, and that he dreaded them exceedingly. It was anything but pleasant to be taken from bed by the head and the heels and dropped into a tub of cold water. The baths had no effect upon the temperature in his case, but when they were stopped, at the earnest solicitation of a relative of his, the temperature subsided, and the fever ran a more favorable course. In Trinity Hospital it was the custom to give typhoid patients sponge-baths, instead of putting them in the tub, and this seemed to him the better way. A rubber sheet is placed under the patient, and the bath given in bed. Most excellent results had been thus obtained. He did not approve of treating any disease in a routine way. In typhoid, the treatment had to be varied to suit the individual. The remarkable statistics of Brand were collected in Germany, and he thought the treatment must be better borne by Germans than by Americans, who seem to be more sensitive. Personally, he had found that careful dieting and the use of castor oil in small doses, every other day, would safely carry many cases of typhoid through the disease.

Dr. Charles L. Gibson said that when he was an interne at St. Luke's Hospital, the bath treatment of typhoid was carried out as a routine measure by Drs. Peabody and Kinnicutt, and it seemed to him to be very severe. He recalled cases of patients who were tubbed as often as seventeen times in the twenty-four hours. The temperature was taken every hour, and as soon as it reached 102.3° F., or over, a bath was given for from five to twenty minutes, usually at a temperature of 65° F. The treatment was hard on the patient, who got no rest at all, and upon the attendants, and at his request the body temperature was taken only every three or four hours, and the baths given less frequently. He was of the opinion that treatment by baths completely changes the type of the disease. Danger of hemorrhage and perforation, however, is not eliminated. He had been especially impressed with the after-appearance of the patients treated by baths, as compared with other typhoid patients. They do not seem to pick up as rapidly as they should, and kidney complications are often observed in the convalescence. They are pallid and anemic, and present the typical kidney aspect. Treatment by baths should be symptomatic. If there is a single high temperature a day, a bath is not necessary.

Dr. S. Baruch said it was an error to say that relapse occurred more frequently in cases which were treated by the Brand method than in others, and that, therefore, this was no argument against the treatment. In regard to the diagnosis of typhoid by the bath, the value of this test had been a revelation to him. He was in the habit of bathing the patient for fifteen minutes in a bath, at 75° F., when there was the slightest evidence of typhoid. This was repeated every three hours, until the temperature was reduced more than two degrees. This test, however, is only of value during the first six days and before the spots appear.

A previous speaker had mentioned the elimination of toxins as the only result of the Brand method of treatment. This is only one of the results; the treatment fulfills every demand of the case. In the first place, it reduces the temperature; secondly, it invigorates the action of the heart, the pulse-rate diminishing in frequency from five to twenty beats after each bath, and, beside the elimination of toxins already mentioned, there is an enormous increase in the quantity of urine passed, sixty-one ounces being quite an ordinary amount, and as much as one hundred and twenty having been noted by the speaker. Another important result of the Brand treatment is the increase of leucocytes in the blood after the baths. By this it was not meant that the leucocytes are produced by the treatment, but that there is such an enormous acceleration of the heart action that they are driven from their hiding-places, so to speak.

He agreed with those who said that routine treatment is bad, but added that the Brand method is not a routine method. It had been thought out under the most definite conditions, the object being simply to improve the condition of the nervous system, which controls all the functions of the body. The baths should be given every three hours, day and night, when the patient is awake, but he is never disturbed for this purpose if he is asleep. The records of 8000 cases of typhoid fever in a military hospital in Germany, covering a period of forty years, during which time there were epidemics of the disease, treated by different physicians, show that just as soon as the Brand method was adopted the mortality was reduced from fifteen to twenty per cent., and that when the mixed treatment (salicylic acid and quinin, with the baths) was employed, this was reduced to seven per cent., and under strict bathing, to 2.7 per cent.

In regard to the case mentioned by Dr. Gibson, where the patient had been given seventeen baths a day, he was surprised to learn that the patient lived to look like a kidney case. Brand never claimed the danger of hemorrhage and perforation is eliminated by the bath treatment, unless the patient was seen before the fifth day, and his 1200 cases show plainly that those patients who died were all admitted after the sixth day. As to the patients treated by the Brand method recovering more slowly than others, the statistics of Vogel, collected in a military hospital, dwell upon this point, and show that the patients were able to go back to their military duty at an early date. He admitted that he thought the treatment harsh and cruel, and that he had seen only one or two patients who did not object to the baths; but he knew of no other method of treatment which produced the same good results, and until such was discovered, typhoid patients must be treated with the means that have been found most efficacious by such men as Delafield and Peabody.

The President said he was extremely surprised to learn of the position taken by the majority of the speakers. He had supposed that the Brand or the Currie-Jürgensen treatment was accepted everywhere, in spite of the disadvantages which Brand himself admits. He had seen excellent results follow this treatment. In Bellevue Hospital it was the custom to give the patients a bed-bath, which is more easily given than the tubbing, and which has the same effect of reducing the temperature, diminishing the nervous symptoms, and causing the patient to sleep. In cases with hemorrhage or perforation, he had seen excellent results follow the use of the cold coil. As it was often impossible for the country practitioner to carry out the tub treatment, he asked Dr. Daniels and Dr. Baruch if bed-baths and the coil could not be used in its stead.

Dr. Baruch replied that he had had no experience with bed-bathing, unless the speaker referred to the sheet-bath, *i.e.*, the patient is wrapped in a wet sheet and enveloped in a blanket; water is thrown on him by the cupful and the body rubbed until it ceased to warm up. He had employed this method while practising in the country, in the Southern States. He did not think it was quite as good as the Brand method, but anything that would give a shock to the peripheral nervous system and a consequent reaction, allowing a quantity of blood to be cooled, would have a good effect and be better than nothing, just as partial asepsis is better than no asepsis.

Dr. Daniels, in closing, said that bed-bathing would answer if good results were gotten from it; if not, it was better to make the patient a little more uncomfortable and give him a Brand bath, for the sake of the good to be obtained. In regard to calling this the Brand treatment, the method he had referred to in his paper was that given by Brand, who had found that by giving baths of a certain temperature, at certain intervals, for a certain length of time, and with friction, the best results were obtained. Dr. Fisk had said that in his case the baths did not reduce the temperature. He had stated in his paper that they had no marked effect on the temperature and that they were not given for that purpose. In regard to the method being a routine practice, the same might be said of the treatment of rheumatism or malaria. The bath treatment could be modified to suit individual cases. In regard to the bad effect of the baths on the nervous system, the case mentioned in the paper of the woman who was seven months pregnant at the time the baths were given, and went on to full term, would disprove this.

Dr. Arthur L. Fisk reported a case of gout, and exhibited a photograph and skiagraph of the patient's hand, which had become deformed during the progress of the disease. (See page 496.)

The President thought the X-ray photographs might prove a valuable aid in the differential diagnosis of this condition.

Dr. Edward K. Dunham reported the following case of aortic aneurism in which the condition was not recognized during life, although there were two large aneurisms—one of the arch of the aorta, and one of the abdominal portions of that vessel. The latter caused death by perforating the diaphragm and rupturing into the pleural cavity.

The patient was a Russian, thirty-nine years of age, who was admitted to the Montefiore Home in October, 1896, and who died March 26, 1897. He was of moderate habits and denied syphilitic infection. His trouble began about two years before his admission to the Home, and first manifested itself by the occurrence of "cramps in the stomach." When he entered the Home he complained of pain in the abdomen, in the back, and in the lower extremities, which was so severe in character as to cause sleeplessness. He was very anemic and much emaciated. The spinal column exhibited a distinct lumbar kyphosis and dorsal lordosis, and the lower part of the thorax was expanded, giving the chest a somewhat bell-shaped appearance.

On auscultation the left side of the thorax appeared to be normal. On the right side the respiratory sounds were absent, except at the apex of the lung and over a small area on the right side of the thorax. These physical signs were due to the aneurism of the arch of the aorta which was discovered at the autopsy. The abdominal aneurism gave rise to a palpable tumor, which was attributed to enlargement of the spleen. The liver was also considered to be enlarged because of its being pushed downward by the thoracic aneurism. There being a suspicion of pernicious anemia, the blood was examined. A few nucleated red blood-corpuscles were discovered, and a slight increase in the number of leucocytes, many of which contained eosinophile granules, was noted, but no indication of the changes characteristic of pernicious anemia was found. On one occasion the urine contained a little albumin, but, with that exception, revealed no abnormal condition.

At the autopsy a spherical aneurism was discovered springing from the right side of the arch of the aorta near its origin which was four inches in diameter. It was filled with firm clots, leaving a clear passage through which the blood could pursue a practically normal course without occasioning any sounds perceptible on auscultation. The innominate artery showed a moderate fusiform dilatation extending from its origin to its point of division. The spleen was normal in size, and was adherent to a large aneurism of the abdominal aorta measuring 8½ inches vertically, six inches transversely, and about three inches antero-posteriorly. The aneurismal sac began as a dilatation of about three inches of the posterior wall of the aorta, and then expanded behind the peritoneum, upward to the diaphragm, and downward for about four inches to a point a little below the bifurcation of the aorta. It dislocated the left kidney and extended to the right across the spinal column, causing an erosion of the last dorsal and first two lumbar vertebræ. The sac had become adherent to and subsequently pierced the diaphragm on the left side, and at this point there was a rupture of the sac, leaving a hole about three-fourths of an inch in diameter through which hemorrhage had taken place into the left pleural cavity, which was found filled with blood at the autopsy. The left lung was compressed and rendered atelectatic, and the heart was displaced to the right by this effusion of blood. The flow of blood through the abdominal aorta did not appear to have been either checked or diverted by the presence of this aneurism, the sac of which was filled with firm and dense masses of clot. These facts explain the absence of any bruit which would have led to a detection of the aneurism during the life of the patient. The middle cerebral arteries on both sides showed numerous miliary aneurisms. The anemic condition of the patient and the changes in the blood are referable to the loss of blood into the aneurismal sacs, and to the consequent attempt to repair the loss of blood-corpuscles.

The case appears of interest because of its obscure nature during the life of the patient, and the proneness of the arteries to aneurismal dilatation without obvious lesions of the vascular walls which would explain their weakness. As yet no microscopic studies of the arteries has been undertaken, and it is possible that, when these have been completed, they will reveal changes explaining the conditions underlying the development of these numerous aneurisms.

DR. HENRY C. COE cited the following cases to show the possible risks of moderate dilatation of the cervix in multiparæ:

CASE I.—Multipara, aged thirty; diagnosis: ruptured ectopic pregnancy, with encysted blood-clot. Cervix had been lacerated bilaterally and had healed, leaving firm cicatrices, especially on the left side. Before opening the abdomen the cervix was gently dilated, first a Wylie and then a Walthan instrument being used. With a separation of a little more than half an inch the cicatrix on the left side suddenly gave way and a deep rent followed, extending up into the broad ligament. After curettement, the uterine cavity was packed with gauze, and the lacerated wound was also lightly tamponed. Celiotomy and removal of the ectopic sac was then done, there being no evidence of internal injury to the broad ligament or of hematuria. Irrigation without drainage was carried out. Uneventful recovery and perfect healing of the cervical tear resulted. The patient has since had two abortions.

CASE II.—Multipara, aged thirty-two; bilateral laceration of the cervix, with extreme induration. Moderate dilatation with Wylie's instrument up to half an inch was performed, when a deep tear occurred on the left side, extending into the broad ligament. Hemorrhage was considerable in amount. After becoming satisfied that the peritoneal cavity had not been entered, a deep wire suture was passed beneath the upper angle of the tear, which controlled the bleeding. The uterus was then curetted, the cervix amputated, and a laceration of the pelvic floor repaired. There was slight febrile reaction on the third day, with pain on the left side. Subsequently, convalescence was normal. When examined a few months later, the patient had a hard, tender cicatrix extending along the base of the left broad ligament, which caused slight deviation of the cervix to that side.

CASE III.—The patient, who was seen in consultation, was a primipara, aged twenty-eight. The operator, an experienced surgeon, was divulsing the cervix preparatory to curettement for incomplete abortion. He stated that on making gentle, steady pressure on the handles of a Wylie dilator, the cervix suddenly tore like wet paper, and there was furious hemorrhage from the left uterine artery. Time was lost in sending for clamps, retractors, etc. He was unable to seize the vessel with forceps, and in order to prevent the patient from bleeding to death, he compressed it with his fingers within the peritoneal cavity until the speaker's arrival, twenty minutes later. He found that the patient had not lost much blood, and was in good condition. Under a good light, he readily succeeded in grasping both ends of the artery, which was undoubtedly the uterine. Two fingers could be passed into the peritoneal cavity through a rent in the posterior fold of the broad ligament, which was partly detached from the uterus. As there was no indication for celiotomy, a gauze drain was inserted, and venous oozing controlled by packing, the clamps being left *in situ*. They were removed seventy-two hours later. An afebrile convalescence followed, the wound healed rapidly, and the patient was up in three weeks.

These cases were mentioned simply to emphasize the importance of exercising more than ordinary care and gentleness in divulsion of a cervix which has healed after a previous extensive laceration, the os being contracted to such a degree that curettement is impossible. The powerful instrument devised by Walthen is certainly a dangerous one to use under such circumstances. In an aseptic operation, mere splitting of the cervix is of slight import, aside from the formation of a large, and often painful, scar. But the injury may be more extensive, as in Case III., involving the risks incident to opening the peritoneal cavity where the aseptic preparation of the vagina may have been imperfect. In any case, it is well not to undertake the simplest gynecologic operation without having at hand the means of controlling hemorrhage and repairing accidental lesions.

Dr. George W. Jarman said he considered the Wylie dilator more dangerous than the Walthen, and knew of two cases in which the fundus uteri had been perforated and one in which Douglas' cul-de-sac had been entered, by it. Laparotomy was done in the two former cases, both of which recovered. In the third case, the wound was carefully sponged after the protruding intestine was replaced, and as there was not much hemorrhage, only one suture was introduced. This patient also recovered. All three cases were drained, for fear the vagina had not been aseptically prepared before the divulsion.

Dr. Johnson of Boston said the parts should be as thoroughly prepared for divulsion and curettement as for an abdominal operation, and cited a case in which death from sepsis followed laceration of the uterus, because the vagina had not been aseptically prepared.

ANNOUNCEMENT.

BRITISH MEDICAL ASSOCIATION.

The sixty-fifth annual meeting will be held at Montreal on Tuesday, Wednesday, Thursday, and Friday, August 31, September 1, 2, and 3, 1897.

PRELIMINARY PROGRAM.

President: Henry Barnes, M.D., M.R.C.S., F.R.S.E., J.P., Physician Cumberland Infirmary, Carlisle.

President-elect: T. G. Roddick, M.D., M.P., Professor of Surgery in McGill University, Montreal.

President of the Council: Robert Saundby, M.D., F.R.C.P., 83A Edmund street, Birmingham.

Treasurer: Charles Parsons, M.D., Dover.

Addresses will be delivered as follows:

"Medicine," Dr. W. Osler, F.R.C.P., Professor of Medicine in the Johns Hopkins University, Baltimore.

"Surgery," Mr. William Mitchell Banks, F.R.C.S., Surgeon to the Liverpool Royal Infirmary.

"Public Medicine."——

The scientific business of the meeting will be conducted in eleven sections, as follows, namely:

MEDICINE.

President—Dr. Stephen MacKenzie, London. Vice-presidents—Dr. J. E. Graham, Toronto; Dr. W. Bayard, St. John, N. B.; Dr. J. P. Rottot, Montreal; Dr. F. W. Campbell, Montreal; Dr. J. Stewart, Montreal; Dr. H. P. Wright, Ottawa. Secretaries—Dr. H. A. Lafleur, Montreal; Dr. W. F. Hamilton, Montreal; Dr. William Pasteur, 4 Chandos street, Cavendish Sq., London, W.

SURGERY.

President—Mr. Christopher Heath, London. Vice-presidents—Sir Wm. Hingston, Montreal; Hon. Dr. Sullivan, Kingston, Ont.; Hon. Dr. Farrell, Halifax, N. S.; Dr. I. H. Cameron, Toronto; Dr. F. LeM. Grasett, Toronto; Dr. James Bell, Montreal; Dr. G. E. Armstrong, Montreal. Secretaries—Dr. R. C. Kirkpatrick, Montreal; Dr. Thomas Walker, St. John, N. B.; Mr. Jordan Lloyd, F.R.C.S., Richmond Hill, Birmingham.

PUBLIC OR STATE MEDICINE.

President—Dr. E. P. LaChapelle, Montreal. Vice-presidents—Dr. Montizambert, Quebec; Dr. R. Craik, Montreal; Dr. P. H. Bryce, Toronto; Dr. Sir James Grant, Ottawa; Dr. R. H. Powell, Ottawa. Secretaries—Dr. Wyatt Johnson, Montreal; Dr. E. Pelletier, Montreal; Dr. Henry Littlejohn, Town Hall, Sheffield.

OBSTETRICS AND GYNECOLOGY.

President—Dr. W. J. Sinclair, Manchester. Vice-presidents—Dr. Wm. Gardner, Montreal; Dr. James Perrigo, Montreal; Dr. J. A. Temple, Toronto; Dr. J. C. Cameron, Montreal; Dr. J. T. Alloway, Montreal; Dr. James Ross, Toronto. Secretaries—Dr. D. J. Evans, Montreal; Dr. W. Burnett, Montreal; Dr. A. E. Giles, 58 Harley street, Cavendish Sq., London, W.

PHARMACOLOGY AND THERAPEUTICS.

President—Dr. D. J. Leech, Manchester. Vice-presidents—Dr. A. D. Blackader, Montreal; Dr. James Thorburn, Toronto; Dr. C. R. Church, Ottawa; Dr. J. B. McConnell, Montreal; Dr. F. J. Austin, Sherbrooke; Dr. Walter George Smith, Dublin. Secretaries—Dr. F. X. L. DeMartigny, Montreal; Dr. J. R. Spier, Montreal; Dr. Charles Robertshaw Marshall, Downing College, Cambridge.

PATHOLOGY AND BACTERIOLOGY.

President—Mr. Watson Cheyne, London. Vice-presidents—Dr. J. G. Adami, Montreal; Dr. J. Caven, Toronto; Dr. J. Stewart, Halifax; Dr. J. C. Davie, Victoria; Dr. L. C. Prevost, Ottawa; Dr. M. T. Brennan, Montreal. Secretaries—Dr. W. T. Connell, Kingston; Dr. C. F. Martin, Montreal; Dr. Robert Boyce, University College, Liverpool.

PSYCHOLOGY.

President—Dr. R. M. Bucke, London, Ont. Vice-presidents—Dr. D. Clarke, Toronto; Dr. T. J. Burgess, Verdun, Quebec; Dr. A. Vallee, Quebec; Dr. G. Wilkins, Montreal. Secretaries—Dr. J. V. Anglin, Montreal; Dr. Geo. Villeneuve, Montreal; Dr. J. G. Blandford, London County Asylum, Banstead, Surrey.

OPHTHALMOLOGY.

President—Mr. Nettleship, London. Vice-presidents—Dr. F. Buller, Montreal; Dr. R. A. Reeve, Toronto; Dr. Ed. Desjardins, Montreal; Dr. A. A. Foucher, Montreal. Secretaries—Dr. W. H. Smith, Winnipeg; Dr. Jehin Prume, Montreal; Dr. T. H. Bickerton, Liverpool.

LARYNGOLOGY AND OTOLOGY.

President—Dr. Greville Macdonald, London. Vice-presidents—Dr. W. Tobin, Halifax; Dr. G. A. S. Ryerson, Toronto; Dr. H. S. Birkett, Montreal; Dr. G. R. McDonagh, Toronto. Secretaries—Dr. Chretian, Montreal; Dr. H. D. Hamilton, Montreal; Dr. W. Permewan, 7 Rodney street, Liverpool.

ANATOMY AND PHYSIOLOGY.

President—Dr. Augustus Waller, F.R.C.S., London. Vice-presidents—Dr. F. Shepherd, Montreal; Dr. A. B. MacAllum, Toronto; Dr. T. Wesley Mills, Montreal; Dr. A. Primrose, Toronto; Dr. J. B. A. LaMarche, Montreal; Dr. D. B. Fraser, Stratford, Ont. Secretaries—Dr. J. M. Elder, Montreal; Dr. W. S. Morrow, Montreal; Dr. Robert Hutchison, London.

DERMATOLOGY.

President—Mr. Malcolm Morris. Vice-presidents—Dr. J. E. Graham, Toronto; Dr. F. J. Shepherd, Montreal; Dr. J. A. S. Brunelle, Montreal; Dr. J. L. Milne, Victoria. Secretaries—Dr. Gordon Campbell, Montreal; Dr. J. M. Jack, Montreal; Dr. James Galloway, 21 Queen Anne street, Cavendish Square, London, W.

REVIEWS.

Diseases of the Stomach. A Text-Book for Practitioners and Students. By Max Einhorn, M.D., Instructor in Clinical Medicine at the New York Post-Graduate Medical School; Visiting Physician to the German Dispensary. New York: William Wood & Co. 1896.

The appearance of a book on gastric diseases from the pen of one who is recognized as an authority on the subject is necessarily of interest. For many years Dr. Einhorn has concerned himself with this chapter of medical inquiry, and has devised methods of examination which have met with more or less approval. The author tells us that it was his design to make this book practical, and by this he evidently means that he leaves scientific questions undecided. That this is the case, we will show later in a few cited instances; but this plan has militated powerfully against the value of the book, for in scientific precision it cannot be compared with the similar works of Boas and of Ewald, and these books, too, are nevertheless practical. Moreover, Dr. Einhorn is capable of writing scientifically, as his published articles have shown.

So far as the contents of the book are concerned, there is little left to be desired in the matter of completeness. The author discusses successively the anatomy and physiology of the stomach, methods of examination, diet, organic diseases with constant lesions, functional diseases with variable lesions, abnormal conditions with reference to the size, shape, and position of the stomach, nervous affections of the stomach, and, finally, the condition of the stomach in diseases of other organs.

In the 478 pages of the book, there is no doubt that, despite the author's evident attempt not to take his readers into too deep scientific waters, very much of value is embraced. The various gastric disturbances, organic and inorganic, are thoroughly discussed, diagnosis and differential diagnosis are exhaustively considered, and therapeutic measures, especially diet, are well presented. But with all this, there is a feeling that the author is concealing something and does not state his own opinion positively enough. The criticism that the author mentions himself and his work too frequently should not be made, in all fairness, since it is *his* experience and *his* opinion that the reader wishes to learn.

Of the omissions, there are not many, Dr. Einhorn even mentioning the Röntgen ray as having some diagnostic value in gastric diseases. He neglects to speak of Kader's method of gastrostomy, and mentions Witzel's method as the latest. He fails utterly to give his opponents a hearing as to the electric excitability of the fundus of the stomach. Of course, Einhorn's electrization of the stomach falls to the ground if Meltzer's experiments are correct; but Meltzer recently (December, 1896) demonstrated before the American Association of Physiologists that the fundus does not contract upon faradic or galvanic irritation, and it would have seemed the part of candor, at least, for Einhorn to have been less dogmatic in his statements in the book under consideration. A record in a text-book is, by that fact, usually regarded as authentic, and it is unfortunate that matters of controversy should be injected as true in a book which is sure to have as wide a circulation as Einhorn's. Experimental evidence, of course, does not impugn positive clinical results, and it is likely that Einhorn's or any other method of electrization of the stomach will be productive of benefit in nervous people, just as the application of the current is helpful in functional neuroses generally.

Transillumination of the stomach is naturally given considerable space, although Dr. Einhorn's method has not met that recognition which he hoped it would. He fails to caution against the use of the gastric diaphane when aortic aneurism is present.

The English is not above reproach. Thus, "there is yet always time" (p. 146), "spikes" for "spokes" (p. 90), "roll particles" (p. 327). In the main, the author's style is flowing, easy, and clear. The illustrations are excellent. Particularly fine are the pathological drawings of Dr. Elsberg, which are worthy of a text-book of pathology. They are well drawn and well reproduced.

This book will have a wide reading, and will probably see many editions. It is, with the exceptions above noted, a good *résumé* of the present knowledge of the subject it considers.

MINOR SURGERY AND BANDAGING. By HENRY R. WHARTON, M.D., Demonstrator of Surgery in the University of Pennsylvania. New (third) edition. In one 12mo volume of 594 pages, with 475 engravings, many being photographic. Cloth, $3.00. Philadelphia: Lea Brothers & Co. 1896.

For the past five years "Wharton's Minor Surgery and Bandaging" has justly held a high place in the regard of medical students. Clearness of cuts and text in the third edition makes the art of surgical dressing and bandaging easily learned. The practitioner will be interested in such authoritatively detailed and faithfully illustrated procedures as amputations, resections, tracheotomy, intubation, etc.

This book is so modern and up-to-date in general that we wonder why space is given to such useless and ancient operations and instruments as the first, second, and third methods of acupressure, Bellocq's canula, scarificator, and sorte-moxa.

PRACTICAL NOTES ON URINARY ANALYSIS. By WILLIAM B. CANFIELD, A.M., M.D., Lecturer on Clinical Medicine, University of Maryland, etc. Second, (revised) edition. Detroit, Mich.: George S. Davis. 1896.

THIS little book is one of the Physician's Leisure Library series, and the author has attempted to point out to the general practitioner, the various methods of examining the normal and pathological constituents of the urine. His efforts are not always satisfactory, and some errors and many repetitions are noted. We do not agree as to the reliability of many of the "test papers" in the examination for albumin and sugar, which are so highly lauded by the author. Most of the illustrations are the ones commonly found in works on urinalysis, but they are poorly executed.

THE DIARY OF A RESURRECTIONIST (1811–1812), to which is added an Account of the Resurrection Men in London, and a short History of the Passing of the Anatomy Act. By JAMES BLAKE BAILEY, B.A., Librarian of the Royal College of Surgeons of England. London: Swan, Sonnenschein & Co., Lim. 1896.

"Ask no questions for your conscience' sake," says Mr. K., the lecturer on anatomy, to his assistant, who is about to receive a body for dissection from the resurrectionists. In such words, Stevenson, in his "Body-snatcher," describes the feeling that was common in the English schools of anatomy in the beginning of this century. For at that time the bodies of executed criminals were the only ones given by law to the medical schools. The supply of material, therefore, often ran short, and the schools had to obtain bodies, often at a high price, from other sources. Thus, body-snatching was winked at by the medical profession, and the body-snatcher or resurrectionist, as he was called, carried on, almost unmolested, his nefarious occupation. He was often a drunken ruffian who hesitated at little or nothing; he bribed custodians of graveyards, desecrated and pilfered graves, and finally, even resorted to murder to satisfy his lust for gold. The notorious murders by Burke, Hare, Bishop, and Williams, led directly to the passage of the Anatomy Act of 1832, which dealt a fatal blow to the resurrectionists' occupation. The "Diary of a Resurrectionist" consists of a series of entries extending over one year, and gives us the actual record of the doings of one gang of resurrection men in London. By far the most interesting part of the little book, however, is the information the author gives us of the origin, workings, and habits of the body-snatchers, and the causes which finally led to their disappearance. We consider the little volume a valuable contribution to the history of medicine.

A TEXT-BOOK ON SPECIAL PATHOLOGICAL ANATOMY. By ERNST ZIEGLER, M.D. Translated and Edited from the eighth German edition by DONALD MACALLISTER, M.D., and HENRY W. CATTELL, M.D. Sections 1 to 8. The Macmillan Co., New York and London. Price, $4.00.

THIS is the first part of Ziegler's Special Pathological Anatomy, and it treats of the blood and lymph, the vascular mechanism, the spleen and the lymph glands, the osseous system, the muscles and tendons, the central and peripheral nervous system and the skin. It is to be followed, very shortly, by a second volume which shall treat of the remaining systems of the body. Ziegler's volumes on Special and General Pathological Anatomy have long been considered by the student and pathologist as the most reliable and resourceful guides to their interpretation of problems in pathogenesis and morbid anatomy. The translators of this volume merit the thanks of English-speaking physicians for the satisfactory manner in which they have performed their task. We do not see wherein they have neglected anything that might have contributed to a more satisfactory presentation of their author's ideas and contributions. The work is up to date, not alone in its subject matter, but in its references; and, fairly so, in its illustrations. Each chapter, or rather the consideration of each subject, is followed by a bibliography, and in many instances this takes up an enormous amount of space compared with the text. Personally, we are of the opinion that the endeavor to consider subjects in a text-book of this kind monographically is a great mistake, and that the space utilized in citing references might be very much better taken up with a fuller discussion of the subject matter, whether it be the views of others, as admitted by the author's experience, or the statement of his individual beliefs.

To the volume is appended an index of more than thirty pages, and we regard this as one of the most commendable features of the work. The book itself will appeal more to the physician and the pathologist than to the undergraduate, and the former will appreciate the copious index. The work contains 308 figures, some of them in colors, most of them very well executed, and they form an attractive feature of the book, which in its general make-up and print is very satisfactory.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXX. NEW YORK, SATURDAY, APRIL 24, 1897. NO. 17.

ORIGINAL ARTICLES.

THE DIAGNOSIS OF GALL-STONES.[1]

BY GEORGE L. PEABODY, M.D.,
OF NEW YORK;
PHYSICIAN TO THE NEW YORK AND ROOSEVELT HOSPITALS;
PROFESSOR OF THERAPEUTICS IN THE COLLEGE OF
PHYSICIANS AND SURGEONS.

Stones in the Gall-bladder.—Gall-stones may remain for years in the gall-bladder without producing any symptoms. It requires but a limited experience in dead-house work to attest the truth of this statement. Yet gall-stones which are too large to leave the gall-bladder, *may* frequently cause severe pain. This occurs when one of them is sufficiently small to engage in the entrance to the cystic duct but cannot make its way into the tube. The cause of this dislodgment may be violence, undue physical exercise, or in some cases the process of digestion.

I saw a case of the latter description a few years ago with Dr. S. Baruch of this city, in the person of a lady about sixty years of age, who was subsequently operated upon by Dr. McBurney. In her case the attacks of pain seemed to be determined by the ingestion of most ordinary food; and her nutrition had suffered in consequence. Her symptoms had persisted for several years, with long intervals of immunity, of course without jaundice; and with the intermittent attacks of pain there was frequently fever of low grade. Her pain was often severe, but not as severe as typical biliary colic, and it was always localized. Complete relief followed the removal of a large calculus from the gall-bladder. Tenderness in the region of the gall-bladder was present during these attacks of pain, but was not a very distressing symptom.

The diagnosis of an *ordinary attack of biliary colic* due to passage of a gall-stone is not difficult, and need not take up our attention.

The complication of other diseases with this distressing series of symptoms has not been common in my experience; but Naunyn speaks of three cases of typhoid fever in which they occurred "in the early weeks," and Hagenmüller has collected reports of eighteen cases of the same disease complicated by biliary colic. The inference has been drawn from these facts, and from the dependence of attacks of biliary colic in some persons upon errors in diet, that peristaltic activity of the intestines tends to cause the discharge from the gall-bladder of stones that previously had not given rise to symptoms, peristaltic activity of the bile ducts and gall-bladder probably being set up by peristaltic activity of the intestines. Physiology teaches that during intestinal digestion the bile is discharged into the bowel in increased amounts in a similar way. Several writers call attention to the fact, as a point of diagnostic importance, that attacks of biliary colic are likely to begin about midnight.

Although the diagnosis is ordinarily an easy matter, still it is possible to confuse such an attack with gastralgia; but in this condition the stomach is likely to be distended with gas, and relief will usually follow its removal. Pressure on the epigastrium ordinarily diminishes the pain of gastralgia, while pressure over the liver region aggravates the pain of biliary colic. Moreover, a chill with fever is much more common in biliary colic than in gastralgia, though this is by no means the rule. The diagnosis is rendered certain if a day or two after the beginning of the attack jaundice develops, if the gall-bladder becomes enlarged and palpable, and if gall-stones are passed by the bowel. But these symptoms are not necessary accompaniments of biliary colic, at least during the first few days. Adler has recently called attention to the frequency with which this disease occurs without icterus. Tenderness over the edge of the liver in the neighborhood of the gall-bladder is a valuable aid in doubtful cases; in the absence of this and other classical symptoms the diagnosis must be left in doubt.

The differential diagnosis between this malady and gastric or duodenal ulcer with severe pain in the epigastrium will sometimes present greater difficulties. Palpation increases the pain of these conditions as it does that of biliary colic. Leube speaks of more than one patient who was supposed for a long time to have this latter malady until a Carlsbad cure brought away biliary calculi in the feces and settled the diagnosis. The possibility of both of these sets of symptoms being set up by the taking of food furnishes an additional element of confusion; but this is much less likely in the case of gall-stones than in that of gastric ulcer, in which latter, too, the *kind* of food is more important as an exciting cause of pain. If the vomited matters contain an abnormally large percentage of acid, this would speak for gastric ulcer;

---

[1] Read at a meeting of the New York Academy of Medicine, April 15, 1897.

although a normal quantity or an abnormally small quantity would not exclude a stomach ulcer or even a duodenal ulcer.

Swelling of the gall-bladder and icterus would speak loudly for the biliary origin of the symptoms, of course, if they happened to be present. This condition might be confounded with lead colic as well as with constipation and intestinal colic; and it resembles some cases of peritonitis very clearly. With renal colic confusion is less likely on account of the very generally classical distribution of the pain in this affection.

Hepatic neuralgia has been described among the possible symptoms which would simulate the affection under discussion, but this seems to me unlikely as it is unusual in its occurrence. I have never met with it, although I am aware that it is said to occur in nervous, anemic people, who are subject to neuralgia elsewhere in the body.

Impaction of calculi in the cystic duct, if it continues, is productive of further symptoms and physical signs. Tait's statement, that impaction of calculi in the cystic duct causes more severe pain than when the impaction occurs in the common duct, has been disputed by Courvoisier, but it certainly does cause severe pain. Death, in collapse, has followed in nine cases of biliary colic, but in these cases the site of the calculus has usually been the common duct. The gall-bladder is sometimes quickly distended by fluid by the lodgment of a stone in the cystic duct, and this may happen long before jaundice indicates the passage of the stone further onward into the common duct. The gall-bladder then becomes palpable as a fluctuating tumor, unless the abdominal wall is very thick. This condition is to be distinguished from a *floating kidney* in a variety of ways. The connection of the tumor with the liver, its movements with that organ during respiration, and the impossibility of displacing it, or causing it to disappear upward, or downward, are all of great assistance in its recognition. It is very confusing if this distended gall-bladder is surrounded, as it sometimes is, by a tympanitic zone. Occasionally, too, the tumor admits of being displaced laterally even beyond the median line.

Another element of confusion is the fact that sometimes the enlarged gall-bladder will vary much in size and distinctness. It will sometimes partially empty itself of its seromucus contents, and become almost, or quite imperceptible. This was noted by Tait in two cases, and by Courvoisier in one. In all three cases the operation disclosed large stones in the cystic duct, and in Courvoisier's one of these formed a ball valve in the canal, which allowed free passage of fluid at times. This intermittent character of the gall-bladder tumor is less surprising when it occurs in consequence of repeated lodgment of different calculi in the cystic, or the common duct.

Muscular paralysis of the gall-bladder is said to occur from over distension, as it does in the urinary bladder. Petit reports a case of this kind. When the patient stood erect the gall-bladder gradually filled; when he laid down, or when pressure with the hand was made upon the fundus it gradually emptied itself. After it became empty bile appeared in the stools. Other similar cases have been reported. Absence of jaundice in these cases would locate the obstruction in the cystic duct.

A fixed tumor of this kind has been mistaken for a liver lobe of abnormal shape, and *vice versa*. I have seen an abnormally pendulous liver, with a tongue-like projection from the right lobe, mistaken for a condition of hydronephrosis; and in that case serious damage to the liver by a surgical operation resulted in the patient's death.

The conjoint occurrence of a gall-bladder tumor with hydatids, in the same case, was very puzzling to Frerichs.

The diagnosis is greatly facilitated in cases of gall-bladder dropsy by a history of previous attacks of biliary colic, followed by a gradually developing tumor at the site of the gall-bladder, which can be traced under the liver, and which lies directly beneath the abdominal wall. This is rendered practically certain if the lower end is convex, its surface smooth, if it allows of some lateral displacement, and moves up and down with respiration. If these signs are present, with local tenderness and fever, and perhaps adhesions to the abdominal wall, one would think of empyema of the gall-bladder. A rough, uneven surface of the tumor and adjacent liver would indicate carcinoma of the liver and gall-bladder.

As Courvoisier says, every tumor in this situation, or adjacent thereto, should be at first suspected of an origin in the gall-bladder. A dilated gall-bladder has been found to occupy the greater part of the abdomen, and has been mistaken for an ovarian tumor. Gall-stone crepitus has been felt when the bladder is full of stones, and its walls are lax, with relaxed abdominal walls. If the obstruction continues unrelieved numerous secondary conditions may develop beside those already alluded to, such as calcification or atrophy of the gall-bladder, or a formation of pouches, or diverticula, which usually contain gall-stones, as well as destructive and other processes in other organs.

Calculi in the Common Duct.—If the common duct be occluded the diagnosis is rendered easier by the invariable occurrence of jaundice. This jaundice may be intermittent in intensity, and sometimes may completely disappear and recur at irregular intervals. This is explained by supposing the obstruction to be intermittent. The jaundice may be followed by serious lesions, or it may persist for years without other developments. A common occurrence, under these circumstances, is the development of catarrhal cholangitis. This may be accompanied by chills and intermittent fever closely resembling true malarial paroxysms in the regularity of their recurrence. If to this is added a large spleen the condition may be very confusing, The differential diagnosis is made by blood examination revealing the absence of the malarial organisms, and also by the impotency of quinin to control the supposed malarial paroxysm.

In some cases a deepening of the jaundice has been noted immediately after each paroxysm. At the time of the paroxysm pain in the liver region is complained of, and gastric disturbance, with vomiting, is not unusual. The temperature often rises to 103°, 104°, or 105° F. The nature of this intermittent fever is still undecided. Charcot believed it to be due to the presence of a ferment in the bile passages. Osler tells us that bacteriology has revealed an invariable infection of the passages with lower organisms; and probably their presence accounts for the recurring attacks resembling ague, as well as for the liability of these patients to suffer from septic processes in general, such as ulcerative endocarditis and pericarditis. The colon bacillus, streptococcus pyogenes and micrococcus lanceolatus have all been found. Hepatic intermittent fever is not peculiar to obstruction by gall-stones, for it occurs in obstruction from any cause, or from pressure by a morbid growth, etc., but it occurs less commonly from such causes than from obstruction by a calculus.

The effect upon the liver of the continued obstruction of the common duct is variable. It is rarely enlarged, but its connective tissue is apt to be increased. An artificial cirrhosis has been produced in rabbits by tying the common duct. Dilatation of branches of the hepatic duct to a varying extent has been observed. This dilatation is sometimes extreme, the canals assuming the size of the small intestines. In one case a cystic dilatation of a duct was mistaken by a surgeon for a gall-bladder, and incised. The mistake was revealed at the autopsy. Dilatation of branches within the liver is sometimes so general as to give a general cystic appearance to the cut surface of the organ. In some cases the liver fluctuates in consequence of these numerous large cavities filled with fluid. Trifling degrees of violence have caused rupture of these thin-walled sacs. Liability to this accident is increased by suppuration, which often accompanies the condition. The contents of these dilated ducts is generally bile, but its color, consistency and translucency all vary greatly. In a few cases it has been a watery fluid quite devoid of the elements of bile.

Suppurative cholangitis is a frequent sequel, with the formation of multiple abscesses in the liver and the supervention of symptoms of pyemia. This condition is, of course, invariably fatal. Its course is marked by a partial fading of the jaundice, and no tendency of it to deepen after the chills, which are likely to occur. Usually the liver is distinctly enlarged, and very tender to pressure. Several such cases have come under my observation.

Perforation of the gall-bladder or of the ducts has frequently occurred. The symptoms of these perforations of course depend upon the other organs involved. Communication between the ducts and the portal vein has been established, also between the gall-bladder and hepatic duct. Perforation into the abdominal cavity is more common, in which case general peritonitis or localized abscesses may result. In one of my autopsies, perforation of the duodenum had occurred; a communication with the gall-bladder was established, which allowed the passage of a large calculus. This was arrested in the ileum and death resulted from intestinal obstruction. Numerous cases of this kind have been recorded by various writers.

I have mistaken the effects of a perforation of the gall-bladder, which was caused by a gall-stone, for appendicitis. Eight or ten years ago a man was brought into one of my wards in the New York Hospital in a very feeble condition with what I believed to be appendicitis. He had fever, and great tenderness and pain in the right iliac fossa, and there was a sense of resistance and some tumifaction and dulness. Dr. Weir, who has published a report of the case elsewhere, saw the patient with me and concurred in the diagnosis. The operation revealed bile-stained fluid in the fossa and a ruptured gall-bladder containing a large calculus. In those cases in which the cecum and appendix are displaced, so as to lie near the gall-bladder, a differential diagnosis between cholelithiasis and appendicitis may not be possible.

Communication with the stomach, jejunum, and ileum has occurred, but is rare. Many cases of opening of the colon have been recorded. The pelvis of the kidney has been opened and it is possible for the urinary bladder itself to be similarly affected in case of a greatly distended gall-bladder. Between the bile passages and the lungs openings have frequently occurred. Bile may be coughed up in considerable quantities. In seven such cases recovery has taken place. This communication with the lung is usually due to other causes than gall-stones, such as hydatids and ascarides with consequent abscess formation. Of all these fistulous communications, that which takes place externally through the abdominal wall is the most common. Courvoisier has collected 184 such cases, in fifty per cent. of which the opening occurred in the right hypochondrium. In twenty-nine per cent. it was in the region of the navel. The number of stones discharged in these cases varied from one to many hundreds. Recovery took place in seventy-eight cases, some with operation and some without.

With the obstruction in the *common duct* by calculi any considerable distension of the gall-bladder with fluid is much less likely to occur than is the case if the cystic duct is obstructed, but if the obstruction of the common duct be due to other causes, gall-bladder dilatation is common enough. This is explained by the belief that in cholelithiasis the gall-bladder has already undergone atrophy in most cases before lodgment of the stone in the common duct; whereas, in obstruction due to pressure from without, no such change in its structure has occurred. Continued irritation of calculi in the common duct, as in the gall-bladder, has been the starting point of carcinoma—less frequently at the former site than at the latter.

For therapeutic purposes, especially from the point of view of surgery, the differential diagnosis between obstruction of the common duct by a calculus and obstruction by other causes, such as external pressure, becomes of great importance. Courvoisier has shown that the following points may be considered important in connection with the diagnosis of obstruction by a calculus:

1. Former attacks of jaundice of short duration.
2. Persistent jaundice of varying degrees of intensity.
3. Jaundice persisting for years.
4. Former attacks of colic, especially if associated with jaundice.
5. Former passage of calculi in stools.
6. Tumor of the gall-bladder, absent or small.
7. Fever of more or less intermittent character.

Calculi in the hepatic ducts sometimes accumulate in large numbers; but hitherto the diagnosis of this condition has not been practicable, owing to the absence of symptoms that could be considered distinctive. Pain without definite characteristics is often present. In some cases it is severe, in others not; in some cases persistent, in others paroxysmal. Vomiting often accompanies these attacks of pain. The size of the liver is not typical; it may be large, normal, or small. Jaundice is not always present, and usually is not intense when it exists. Intermittent fever may occur. Under these circumstances it is not surprising that this condition is hardly ever suspected during life, and is discovered at autopsy as a surprise.

THE TREATMENT OF CHOLELITHIASIS.[1]

By W. GILMAN THOMPSON, M.D.,
OF NEW YORK;
PROFESSOR OF MATERIA MEDICA, THERAPEUTICS, AND CLINICAL MEDICINE IN THE NEW YORK UNIVERSITY; PHYSICIAN TO THE PRESBYTERIAN AND BELLEVUE HOSPITALS.

The medical treatment of cholelithiasis is considered naturally under the heading of (I.) the treatment of the attacks of colic, and (II.) that of the intervals, or the use of prophylactic measures.

I. *Treatment of the Attacks.*—The pain of hepatic colic excited by the passage or impaction of one or more gall-stones is often among the greatest physical agonies with which man may be afflicted, and demands prompt and vigorous measures for relief. It is comparable only to the pains of childbirth, angina pectoris and nephritic colic. From ¼ to ½ of a grain of morphin, with $\frac{1}{100}$ of a grain of atropin should be injected at once, preferably in the hepatic region, and from 15 to 30 minims of spirits of chloroform should be administered in cherry-laurel water, either alone or with ʒ j of Hoffman's anodyne. The chloroform acts as a local anodyne, and also tends to lessen the spasms of the walls of the biliary ducts which is believed to exist. Being promptly absorbed by the stomach, the chloroform passes into the portal system and directly reaches the liver. Belladonna and sulphuric ether may be employed for a similar purpose, but they are usually less effective. A large, very hot flax-seed poultice should meanwhile be applied over the region of the gall-bladder, and maintained there for several hours. If the pain admits of the patient being moved into a bathtub, complete immersion of the body in water at 104° or 106° F., is often soothing. Should these measures fail, the production of the first stage of chloroform narcosis, as in labor, is indicated.

Relief of the colic by no means indicates betterment of the local condition, and a much more complex question is that of the possibility of accelerating the passage of the stone or stones. Theoretically, this might be accomplished (*a*) by increasing the driving force behind the stone, namely the hepatic pressure, the gall-bladder contractile power, or the peristaltic action of the gall-ducts; (*b*) by lessening the resistance in advance by facilitating the relaxation of the muscular walls of the ducts; (*c*) by reducing the size of the stone by some solvent. Unfortunately, however, the solution of these problems has thus far proved most discouraging.

a. To increase the expulsive force, the so-called cholagogues, such as podophyllin, calomel, etc., have proved of little avail, for they are too slow and uncertain in action to relieve the immediate attack.

---

[1] Read before the New York Academy of Medicine, April 15, 1897.

Massage of the gall-bladder, with the object of forcibly expelling the stone or of stimulating contraction of the bladder, has been attempted, but, as a rule, it is impracticable and dangerous during the attack. The hepatic region is not very accessible to such treatment, is often too painful, and the gall-bladder itself is by no means always palpable—it may even be reduced in size by spasmodic contraction. Moreover, if the stone has caused abrasion, inflammation or ulceration of the duct, perforation may be produced by forcible handling of the patient.

At best the hepatic pressure is very low, and the main propelling force of the stone is in the peristaltic contraction of the gall-bladder and ducts. Drugs which, like strychnin, stimulate peristalsis in general, are far too slow and uncertain to be relied upon in the emergency of biliary colic. Irrigation of the colon by cold water is believed to excite a reflex peristalsis of the biliary passages, but it has been more successful in catarrhal duodenitis than in cholelithiasis.

b. To lessen spasm the best remedies are those already mentioned for the relief of pain, namely morphin, belladonna, chloroform internally or by inhalation, and external heat.

Much has been written during the past few years of the value of olive oil in large doses. This treatment is an old method which was revised by Sée, Rosenberg, and others, about eight years ago. The oil is given upon an empty stomach in quantities from two ounces to a half pint, when it is believed to pass promptly into the duodenum. The ordinary commercial oil is often irritating when used in such doses, therefore care must be taken to secure a pure preparation. It has been shown by Burbank that after the administration of oil in this manner, masses of inspissated fatty acids, soap, and mucus are passed from the rectum, which have no doubt in many instances been mistaken for small gall-stones.

I have given this treatment a thorough trial, but have failed to be convinced of its benefit. One patient at the Presbyterian Hospital passed a large number of genuine facetted stones shortly after taking the oil, but another, seen during the past season at Bellevue Hospital, took over 100 ounces of oil in divided doses during a period of two months, without any appreciable effect upon her attacks, which increased rather than lessened in frequency, with deepening jaundice, enlargement of the gall-bladder and intense paroxysms of colic, returning every few days. In still other cases I have observed no effect at all attributable to the oil, nor is it easy to understand why there should be any. The explanation of its action, which has been advanced by some authors, that the oil "lubricates" the passages is almost too absurd for serious consideration. It is not a function of the common bile duct to absorb oil or anything else from the intestine, and it is an elementary physiological fact that even when taken in great excess, fats and oils are absorbed almost exclusively by the lacteals, and hence enter the lymphatic vessels rather than the radicals of the portal system, and their further course is too remote to admit the belief that they can ever reach the mucous lining of the gall-ducts.

Enthusiastic believers in the efficacy of treatment by specific remedies are apt to forget that there is much in coincidence. It may easily happen that a stone has nearly completed its passage at the time when a medicine is given, and medicine and stone may happily reach the intestine together without the slightest relation of cause and effect. It must be acknowledged, however, that a large number of experienced clinicians have reported cases favorably treated with olive oil, cases in which repeated attacks of biliary colic have not only been relieved, but in which other prominent symptoms, as jaundice, local tenderness, swelling, etc., have promptly disappeared. In explanation of these cases Weil suggests that the oil has a soothing effect upon the mucous surface of the duodenum, which in some manner is reflected to allay irritation in the bile ducts. He claims to have derived similar advantage from its use in several cases of passage of renal calculi.

c. The hope of reducing the size of the stone *in situ* by any of the present medicinal means is as futile as are the attempts to dissolve renal or vesical calculi when once formed. Chloroform and ether are both good solvents of cholesterin, but it is highly improbable that they can reach an impacted calculus in sufficient strength to act upon it when given in justifiable dosage.

Permanent impaction is the exception, not the rule, and in the majority of cases, like the child during labor, the stone is extruded without medicinal aid, although the process may be extremely tedious and painful. The chief indication for the treatment of the attack is, therefore, to mitigate the suffering of the patient.

II. *The treatment of the intervals*, or the prophylactic treatment, would be more promising were the bile a less complex fluid, and if gall-stones were not found from time to time in almost all classes and conditions of patients, their existence being often the discovery of the pathologist and not of the clinician. According to Schröder, they are present in twelve per cent. of all autopsies. Theoretically, however, the prophylaxis would similarly fall under three headings: (*a*) The prevention of hepatic engorgement and of the accumulation of bile in the liver or gall-bladder. (*b*) A dietic regimen, withholding such foods as are likely to eventually furnish the elements of cholesterin in excess. (*c*) The giving of sufficient fluid to in some degree dilute the bile and prevent too great viscidity of the vesical mucus.

a. The prevention of hepatic engorgement is to be accomplished (*a*) by familiar hygienic measures and (*b*) by cholagogues and cathartics. Alcoholic stimulants, over-eating, tight-lacing, and sedentary habits with cramped positions are to be particulary avoided, while exercise in the open air, especially that form of it made expressly for the liver, horseback riding, should be encouraged. As hepatic stimulants and cathartics, a host of drugs have been prescribed. Prout and Harley strongly favor the use of sodium bicarbonate in doses of from half a dram to one dram, which may be given in a pint of hot water at bedtime, while Bouchard prefers acetic and citric acids. My own experience coincides with that of many others in obtaining the best results from sodium phosphate. A dram or two of the salt should be given in bitter infusion or in hot water on rising in the morning, and an equal quantity of glycerin may be added with advantage. If this dose does not keep the dejecta free and well colored, it should be repeated once or twice later in the day. By some, Carlsbad salts are preferred, and the Carlsbad "cure" itself has many advocates. A good dose of blue mass or of calomel once or twice a week is serviceable in robust or plethoric subjects. Abdominal massage will benefit the obese.

b. Dietetic Treatment.—I have as yet to find any special menu which yields satisfactory results in many cases of hepatic calculi, yet it is well to regulate the patient's diet within certain limits, for the presence of gall-stones is often related to excesses of the table in regard to both food and drink, and food which increases the acidity or lessens the alkalinity of the secretions is believed to favor the precipitation of the deposits. In the opinion of Frerichs, this is further aided by too long intervals between meals, which allow of the accumulation of bile in the gall-bladder.

Among other explanations of the formation of the stones is a preponderance of fat in the diet, although cholesterin is not a true fat, but an alcohol allied to fat in some of its properties. Dujardin-Beaumetz, on the other hand, abandons the proscription of fats and carbohydrates, and gives eggs, starches, green vegetables and fruit, directing his patients to avoid fish, meat, and alcohol.

Among several cases of biliary colic that I have lately seen, one was that of a Russian peasant woman, forty-six years of age, who had lived very largely upon fish for several years, and another that of a man of thirty-two years, who had been all winter at a Long Island farm, having no fresh vegetables, but a few potatoes, and subsisting mainly upon salt meat—yet I do not attach much importance to such dietic observations. Graham of Toronto reports a case of fatal hemorrhage in a woman of seventy-six years, whose gall-bladder was full of calculi, and who had subsisted for a long time previously upon potatoes, bread, and sweets.

Glisson favors a diet for man consisting largely of green vegetables, because he found gall-stones to be present oftenest in cattle and sheep in the springtime after they had lived upon dry food all winter, but Graham attributes this rather to lack of exercise. The fact that these stones are common in herbivores does not necessarily furnish argument for dietic treatment in man, for their bile is of somewhat different composition.

Harley, who has given more attention than any other author to the prevention by dietic treatment of a return of cholelithiasis, called attention to its greater prevalence in cold latitudes than elsewhere, and attributed this fact to the influence of certain foods, especially meat, fat, and suet. He wrote: "Starchy puddings and fat bacon cause more gall-stones in this country (England), I believe, than all the other kinds of food put together." The hydrocarbons are more completely consumed during early years than after middle life, and to this, possibly, is due the greater prevalence of gall-stones in the latter period.

Bauer believes that "the formation of gall-stones may often be referred to a faulty diet, for an excessive consumption of meat or free indulgence in fat and in spirits, would probably favor their formation"—yet the Eskimos are nowhere mentioned as being especially prone to their formation, and the members of the Nansen expedition lived in perfect health for nearly three years while subsisting largely upon meat and fats. Nansen writes ("Farthest North," vol. ii, p. 540) that he gained nearly twenty-two pounds in weight, and one of his companions gained over thirteen pounds, and adds: "This is the result of a winter's feeding on nothing but bear's meat and fat in an Arctic climate." Nevertheless, animal food may itself contain cholesterin and should therefore be eaten sparingly by those who are subject to biliary colic. Calves' brains, and the viscera of animals used as food in general, and particularly the liver, must be wholly forbidden. It is well also to forbid sugars and fats in every variety. Some vegetables, such as peas and carrots, are believed to contain material which closely resembles cholesterin. Carrots, moreover, are sweet, and sweet vegetables and fruits should be avoided, as should butter, and also egg-yolks, on account of the fat which they contain. Fresh green vegetables and acid fruits which, by virtue of their alkalin salts and organic acids, easily combine in the blood with alkalin bases, should make the basis of the diet in cholelithiasis. The potassium salts, which are contained in potatoes and other vegetables in abundant quantity, are believed to be serviceable because they retard the liberation of calcium, which has been shown to precipitate cholesterin. Bread and well-cooked cereals and fresh fish (except salmon, mackerel, and trout which are fat) may be eaten. Chicken or lean beef may be allowed, but all meat should be eaten very sparingly and not oftener than once a day.

c. The Use of Fluids.—For the purpose of diluting the blood, and through it the bile, large quantities of fluid should be ingested, but it is best to avoid the aerated waters and mineral waters containg salts of lime, although other alkalin waters are very beneficial. Pure waters like the Poland, which contain a minimum of mineral ingredients, are good, although they do not possess any great advantage over ordinary water, if the patient can only be persuaded to drink it freely. A tumblerful of hot water may be drunk at night, and another on rising in the morning. Champagne and other beverages which hold much carbonic acid gas in solution must be avoided, as must malt liquors. In fact, the patient is usually better without alcohol in any form, although a little claret may be allowed if necessary. Coffee and tea may be taken in moderation, but milk, from its tendency to produce "biliousness," is not recommended.

If the case be one in which considerable gastric catarrh or dilatation of the stomach is present, it is inadvisable to give much fluid by the mouth, and sometimes the desired result may be obtained by injecting salt solution into the colon. Intestinal irrigation, as well as active purgation, favors removal of the bile and prevents its accumulation in the gall-bladder.

In conclusion, the prophylactic treatment recommended as being, on the whole, most satisfactory, consists of the daily use of sodium phosphate with glycerin, and a moderate diet from which fats, sweets, and alcohol are excluded, and meats reduced to a minimum, with an abundant supply of simple fluids as diluents. It may be added that while the therapeutist often gropes in the dark in vain efforts to reach the hidden calculi, the surgeon can now throw full light upon them by operations which promise not only relief but permanent cure, with a measure of safety which is constantly increasing. In cases in which jaundice or local tumor and tenderness persist, and particularly where there is prolonged elevation of temperature, or where the attacks of colic return with increasing severity or frequency, it is worse than useless to temporize with medicinal agents, and the remedies above enumerated are applicable only for temporary relief of colic, or in mild cases, or when the patient refuses operation.

SOME REMARKS ON THE SURGERY OF THE GALL-BLADDER, AS INFLUENCED BY ANATOMICAL SITUATION.[1]

By ARPAD G. GERSTER, M.D.,
OF NEW YORK;
SURGEON TO MT. SINAI HOSPITAL; CONSULTING SURGEON TO THE GERMAN HOSPITAL.

As THE time allotted to me is necessarily very brief, I shall not attempt an exhaustive exposition of all the important factors to be considered in the treatment of the surgery of the gall-bladder, but will confine myself to sketching the variations in the anatomical situation of this organ, and the manner in which these variations will influence the surgical therapy directed against maladies caused by gall-stones.

The first object of all surgical measures directed against the various affections of the gall-bladder is the *exposure* of that organ Ordinarily, and fortunately so, this is a comparatively easy matter; and this is partially due to the fact that the gall-bladder is normally situated in the anterior part of the external longitudinal fissure of the liver, and therefore is to be found near the anterior margin of this gland, and partially to the following circumstances: In many, I might say most, cases of gall-bladder trouble, considerable distension of this organ exists, which has a pronounced tendency to elongate its main axis, and, as a result of this, we find the gall-bladder prominently projected downward and forward, so that it can easily be touched through the abdominal wall. In suitable cases, when the abdominal walls are thin, the presence of a tumor of the gall-bladder can be observed by the eye, also, in the shape of a roundish, pyriform mass, rising and falling with the movements of respiration.

In women suffering from gall-stones (and these make up the great majority of the sufferers from cholelithiasis) another circumstance tends to facilitate the finding of the gall-bladder, in a large proportion of cases, namely, the characteristic elongation downward, a tongue-like projection, of the right lobe of the liver, so often found as a consequence of habitual tight lacing. When the common duct also is obstructed, the liver, as a whole, becomes intumescent, and is found projecting several inches downward beyond the costal margin.

Whenever these conditions prevail, and the gall-bladder can be felt in the shape of a characteristic tumor, an easy operation may be expected, as far as the anatomical circumstances are concerned. A small longitudinal incision, carried through the abdominal wall over the long axis of the tumor, will at once expose it, and frequently the mass can be brought out of the abdominal cavity, and the subsequent steps be attended to, extraperitoneally. The safest procedure is to put a gauze packing around the protruding gall-bladder, to prevent its slipping back and to guard against soiling the peritoneum; then to evacuate its liquid contents by aspiration; finally, to incise and remove the concretions from the gall-bladder, or the cystic duct, by suitable manipulations. A small calculus forceps, or a blunt, spoon-shaped scoop, will be found very useful. If the dislodgment of a stone in the cystic duct is impossible by these means, the subsequent steps ought to be as follows: The gall-bladder must be thoroughly wiped out and dried with small sponges held in a long forceps; the edges of the cystic incision should be pulled forward and held up by assistants, while the operator removes the packings, one of the assistants being charged with guarding the cystic orifice with a sponge, held in a proper manner to catch escaping blood and secretions. Now the operator passes his index finger along the under surface of the gall-bladder into the abdominal cavity toward the cystic duct while his scoop or forceps is made to approach the concretion through the interior of the organ. A combined manipulation of finger and instrument will often be crowned with success. If this does not succeed, two fingers may be passed down to the stone, and another trial be made. Should this also fail, the external incision must be sufficiently enlarged, either longitudinally or transversely, to enable the surgeon to expose and reach the site of the impaction. A crushing of the concretion by finger pressure may be tried, but will not often succeed, and then, the surrounding peritoneal contents being suitably protected by gauze packing, the cystic duct is sufficiently incised over the stone to permit of its extraction. A gush of bile—usually more or less infected—will follow the extraction, and will have to be caught in sponges. If the duct be much dilated and hypertrophied, the place of the incision easily accessible, and the patient's condition good, the little wound may be closed by a few fine silk or catgut stitches, which must not include the mucous lining. This suture, however, is not necessary, as the tendency to spontaneous closure of the incision is very marked. In case it is decided not to suture the incision a drainage tube is placed so as to inosculate, as it were, with the slit, and packings are carried down around it to the duct, surrounding it on all sides in the manner of a well. Then the first soiled packings may be withdrawn, or, if the contents of the gall-bladder were manifestly purulent, should be left intact for a few days, after which they may safely be removed, and the external opening reduced in size by secondary abdominal suture. I have found a transverse incision through the abdominal walls very useful in giving access to the deeper bile passages, and whenever I find the first longitudinal incision inadequate, I always add a transverse one, making the wound L-shaped. The tendency to the formation of hernia is very slight in this part of the abdominal wall.

---

[1] Read at a meeting of the New York Academy of Medicine, April 15, 1897.

Some additional points to be observed whenever a gall-bladder is to be incised may also be mentioned. Often while aspirating cystic contents the needle will bring out clear serum at first, and for a considerable time. But this should not delude us into believing that we are dealing with a simple hydrops of the gall-bladder, as the corpuscular elements of pus have a tendency to gravitate toward the neck of the organ which is nethermost in the recumbent posture, permitting clear serum to collect at the top. Therefore, whenever relaxation of the walls of the gall-bladder has proceeded far enough to permit of the fixation and extraction of the cyst from the abdomen, the patient should be turned over on the right side, the wound being well down, and suitable provision made to direct the escaping contents away from the packings guarding the peritoneum. It will be seen as a rule, that the last gush of liquid emerging consists of thick, glairy pus. A careful toilette of the interior of the gall-bladder, and a change of all soiled packings, should precede any further steps.

The more acute the general and local symptoms, and the more prominent the signs of sepsis, the more painstaking should be the care and caution of surgeon and assistants. When the state of a gall-bladder is approaching the condition of phlegmon, characterized by the presence of free ascitic fluid in the dependent parts of the peritoneum, by intracystic suppuration, or multiple foci of suppuration in the wall of the gall-bladder—occasionally reaching the acme of these processes in the shape of gangrene, the procedure should be directed in the first line toward safe evacution, *and that only.* The same principles prevail here as obtain in evacuating a circum-appendicular abscess, and all avoidable manipulation and exposure should be carefully shunned. Search for stones is only permissible as far as it is easily carried out, and the surgeon's eagerness should not be allowed to compromise the patient's recovery from impending sepsis. As soon as the septic element is out of the way, it will be time enough, and much safer, to institute a search for stones, which, by the way, may become entirely unnecessary through their spontaneous evacuation, which is not at all rare.

In a case of phlegmon or gangrene of the gall-bladder, even much stitching of the organ to the abdominal walls should be avoided. The sutures will not hold in the brittle and rotten material, and chief reliance should be placed on a comprehensive and adequately distributed packing. But when the bladder walls are sound, it is proper to fasten them to the abdominal walls by suture, and when the contents of the gall-bladder have been innocuous and a thorough toilette possible, or when the manipulations have been all carried on outside of the peritoneal cavity, the suture may be so arranged as to accomplish at the same time a closure of the abdominal wound. To facilitate this, the parietal peritoneum is first attached to the edges of the cutaneous incision by a number of cutgut sutures; then the peritoneal covering of the gall-bladder is neatly sewed to the everted parietal peritoneum all around, which finishes the procedure. For this latter suture fine silk is preferable to catgut. In very fat subjects, or in the presence of the bronchial or pharyngeal catarrhs of elderly people, a more carefully made, and double or treble line of sutures will be necessary to prevent possible rupture and the escape of gut during fits of coughing. Even so, accidents will occasionally occur, even as late as a fortnight after the operation, as happened in my own experience two years ago.

As you have noticed, I have laid especial emphasis upon the consideration of the anatomical relations of the gall-bladder, as they affect the various surgical procedures demanded by morbid conditions of that organ. So far, we have discussed the steps usually employed in what may be called a *normal* state of affairs. Let us now examine what is fortunately *unusual*, though not rare in the situation of the gall-bladder. Often, the gall-bladder is found embedded in a maze of adherent omentum and gut, but this does not prevent or materially impede access, as separation, blunt or by cutting, will readily open the way to the goal. Great difficulty of access, however, is caused by a deep situation of the gall-bladder, that may be due to one of two causes: The gall-bladder may be located very far back on the under surface of the liver, or the liver itself may be situated very high up behind the thoracic wall. And if you add to this that the gall-bladder itself may be shrunken and atrophied to a little sac, contracted around a nodule consisting of a nest of stones, you will have an ensemble of all those conditions which render cholecystotomy uncomfortable and difficult.

I have, at the present moment, examples of both of these combinations occupying beds at Mt. Sinai Hospital. In one case there was an unmistakable history of gall-stone colic, but no tumor could be demonstrated. The lower margin of the liver could not be felt, and dulness on percussion began fully three inches above the costal arch, extending correspondingly higher than usual along its upper limits. The edge of the otherwise normal-looking liver could be seen only after two of the lowermost ribs had been excised, and even then the situation of the shrunken gall-bladder was so deep that attachment to the abdominal wall was out of the question. A large horizontal incision had to be made to enable us to expose the organ by extensive packing away of the viscera. A formal well of gauze was built up from under and behind the gall-bladder up to the surface, and this cylindrical space was firmly plugged up by another system of gauze packings, the latter being marked. Twenty-four hours later the core of the packing was removed, whereupon the shining apex of the gall-bladder appeared in the bottom of our well. Incision released a moderate quantity of pus and glairy mucus, and thirteen stones were extracted, the last one from the cystic duct. Bile began to flow immediately. Four days latter the first packings were all replaced by fewer and smaller ones. The patient, a woman of thirty-two, is doing very well.

In the other case we had the combination of a contracted gall-bladder, which was situated very far back in the external longitudinal fissure and deeply embedded in the parenchyma of the liver itself. We proceeded similarly in this case also, doing the operation at two sittings, and evacuating several semi-solid tenacious concretions. This patient also is convalescent.

Of the so-called "ideal cholecystotomy" I have no personal experience. It consists in the evacuation of the cystic contents, and immediate occlusive suture, both of gall-bladder and abdominal wall. It seems to me, that the advantage of an immediate restitution of normal anatomical conditions is not counterbalanced by the dangers of possible leakage due to imperfect drainage toward the duodenum.

Whenever the gall-bladder, or cystic duct, is found to be changed in such a manner as to justify the suspicion of a neoplasm, it is proper to excise it. The technic of cholecystectomy is also much influenced by the anatomical situation of the organs in question. In addition to the relations enumerated, may be mentioned the fact that the gall-bladder has occasionally a complete peritoneal investment, and this is attached to the liver by a perfect mesentery, containing nutrient vessels, which must be secured by ligature before being severed. Occasionally the gall-bladder is completely buried in the parenchyma of the liver. Between these two extremes all gradations may be observed, the most common arrangement being that the upper surface of the gall-bladder is attached to the liver by loose connective tissue, the rest of its surfaces being covered by peritoneum. According to these variations, and dependent upon its superficial or deep situation, excision of the gall-bladder will be an easy or a difficult undertaking. Separation from the liver by blunt dissection will be easy, and the hemorrhage from the raw hepatic surface can be readily controlled by packing and pressure. The pedicle, consisting of the cystic duct, is to be tied firmly before the gall-bladder is cut away. As the ligature may easily cut through brittle structures, causing leakage, it will always be safer to drain than to occlude completely.

Cholecystenterostomy, that is, the establishment of an open communication between the gall-bladder and the gut, is indicated in the presence of a hopeless obstruction of the common duct by a neoplasm or intractable stricture. It is most readily accomplished by means of Murphy's button, which can be applied rapidly and with a considerable degree of safety, the former a most important element in dealing with individuals generally weakened by neoplastic cachexia and victims more or less of cholemia.

PRACTICAL OBSTETRIC NURSING.

By CLARENCE KING, M.D.,
OF MACHIAS, N. Y.;
PHYSICIAN TO THE CATTARAUGUS COUNTY HOSPITAL.

IN ancient and medieval times, when the practice and art of medicine was enveloped in superstition, but little attention was paid to the nursing of the sick, and it was not until the advent of the Crimean war that any organized effort was made to give it a practical application as an auxillary to the treatment of disease. Now, it has been so far developed as to constitute both a science and an art, and training schools for the thorough education of young adults in nursing have been established in connection with all large hospitals. Nevertheless, by far the greater part of nursing, especially of obstetric cases outside of the maternities, is done by those who have had no systematic training for such work; and it is largely due to this fact that we meet with so many serious complications in connection with midwifery cases, some of which are fatal to mother or child, while others entail a prolonged illness or a life of future invalidism to the unfortunate victims.

The proper nursing of obstetric cases begins, in my opinion, as soon as the woman knows that conception has taken place. During the first seven months, in by far the greater number of cases, this need consist of only extra care as regards personal hygiene, combined with the application of rational ideas in relation to dress. The corset should be laid away, the clothing loosened, and the skirts hung from the shoulders. Moderate exercise in the open air should be taken when the weather will permit; and the various excretory functions of the body should be kept active by means of diet, frequent baths, followed by brisk rubbing, and the ingestion of liberal amounts of pure water. In case nausea and vomiting are severe, they should receive attention from the family physician; if slight, they may be controlled by regulation of the diet, which should be easily digestible, and include milk, eggs, and fruit in liberal quantities. I do not believe in the practice advocated by some of restricting the diet to certain articles deficient in the bone-forming constituents, with the idea of rendering labor less painful. Such a process of semi-starvation must be injurious to both mother and child, while at the same time it but imperfectly accomplishes the result desired.

By far the most serious complication to which the pregnant woman is liable is structural disease of the kidney, by which the excretion of the various poisons suspended in the urine is prevented. This disease is generally considered to be due to the pressure of the enlarged womb upon the ureters, and obviously this is most apt to occur when intra-abdominal pressure is the greatest, that is, during the last month of pregnancy, although cases of renal involvement have been reported as early as the fourth week. If neglected, in about thirty per cent. of cases, such lesions will terminate in general convulsions, coma, and death. Fortunately, most cases are attended by albuminuria, and this can readily be detected by examination of the urine, which should be tested frequently during the last month of gestation. The other symptoms which indicate nephritis, and which should always excite alarm, whether accompanied by albuminuria or not, are scanty secretion of urine, severe or frequently recurring headaches, dropsy, especially of the eyelids and face, and disturbances of the special senses, as manifested by persistent ringing in the ears, dimness of vision or flashes of light before the eyes. A few cases occur where these symptoms are very mild or transient, yet, ordinarily, the patient or her nurse, if aware of the serious import of these symptoms, will be able to discover some evidence of nephritis in every case where it exists. The disease is most apt to develop in women pregnant with their first child, and as they are naturally timid about consulting a physician, or suppose their symptoms are the natural and necessary result of their condition, they let the golden opportunity pass, in the vain expectation of soon being better. Every expectant mother should place herself under the watchful care of her physician as early as the beginning of the eighth month. She should also notify him in advance as to the time of her expected confinement, so that he can arrange his affairs, as far as possible, to be with her when needed. Some authors hold that the physician should examine every patient during the last month of pregnancy, to ascertain the position of the fetus *in utero*, and, if unfavorable, to correct it. I cannot endorse this fully, as in about ninety-five per cent. of all cases the head presents, and hence requires no interference; while in the five per cent. in which we find a faulty presentation, we can remedy it, before the onset of labor, only in a very small proportion of cases. However, when a previous child has presented by the breech or shoulder, it is an excellent rule to follow.

As the breasts increase in size during pregnancy they should be protected from pressure, and the nipple, if depressed, should be drawn out by the fingers or suitable suction apparatus several times a day. It is generally advised that the nipples be hardened by bathing with brandy or cologne-water, but Keating takes exception to this. He claims that if the woman begins handling the breasts early she will gradually accustom the nipple to rough manipulation, very much the same as a baseballist's hands are hardened by constant practice. In case the weight of the breast or tension within it becomes so great as to cause distress, it may be relieved by thoroughly anointing it with vaselin or cocoa butter and applying a supporting bandage.

Previous to labor the woman should provide herself with at least two bandages or binders, to be worn by her during her confinement to bed. Whatever arguments may be advanced against the use of the bandage, it is still a fact that it gives support to the flaccid abdominal walls, and is generally gratifying to the patient; besides, it affords an opportunity to fasten the napkins in place. The bandage should be about ten inches wide, with darts over the hips to make it fit the body, and should have a perineal piece about four inches wide. I cannot recommend the use of buttons or buckles to fasten the bandage, as I have found them unsatisfactory, and hence prefer common pins. I apply the bandage tightly at first, but after two or three hours have it loosened if it does not become so from the further contraction of the womb and adjustment of the abdominal organs.

As soon as labor begins the physician, or midwife, and the nurse should be summoned; and here a few words of advice are necessary. My father used to say that people always sent either fools or children after the doctor, meaning thereby that he was seldom able to ascertain anything from the messenger about the patient he was to see. It is very important, especially in cases where the physician has not been engaged in advance, that he be told before leaving his office that the case is to be a confinement; and it is still more important if it is an abortion, for he will then almost certainly need his obstetric instruments. He should not be called until it seems certain the woman is in labor, and the messenger should be able to give her history and subjective symptoms up to the time he left home.

The bed should be prepared by removing the feathers and spreading a heavy blanket on the mattress, and over this a sheet. Then a sheet should be folded so it will be about eighteen inches wide by thirty-six long and placed crosswise of the bed where the patient's hips will come, and on top of this one of her prepared bandages. Over all this a rubber sheet should be arranged—which sheet, by the way, every accoucheur should carry in his satchel—and on this a small blanket or folded sheet, or, better still, a layer of absorbent cotton quilted on heavy paper, as this can be burned after labor is completed. The bed-room should be large so as to give ample room, and the patient should lie so that her head will be at the physician's left hand as he faces the bed. She should be clothed in her night garments, and have a folded sheet pinned around her waist, next her body, with the pin over her right hip, and, as she lies down, should have her clothing pulled up above her waist. By means of this her bed and clothing will be kept dry, and after the soiled clothes are removed there will be no need of changing her to another bed. A couch or lounge is very undesirable for a confinement cot, as it is too low and too narrow to be convenient for the attendant.

While waiting for the physician the patient should have an enema of soap suds to unload the bowels, and should also receive an antiseptic vaginal douche, especially if she has had any leucorrheal discharge. The external genitals and adjacent parts should also be thoroughly bathed with a 1-to-2000 sublimate solution. The woman is then ready for examination. For this purpose she should lie on her left side with her hips near the edge of the bed and her knees drawn up. The physician, after thoroughly warming and disinfecting his hands, should examine thoroughly to ascertain the progress made and also learn, if possible, the position of the fetus in the womb. After this, if the labor is not too far advanced, the woman may be allowed to sit up or even be encouraged to walk about. The conversation in the lying-in chamber should be of a cheerful nature, and the mention of recent deaths or of cases of serious sickness are wholly out of place. Likewise it is best that the nervous and over-sympathetic mother, unless able to control herself, should be excluded from the room; but at least two efficient assistants, in addition to the nurse, should be in attendance.

At the onset of labor, the nurse should provide the following articles, in addition to those already mentioned: A liberal supply of both hot and cold water, wash-bowls, soap and towels, one or two extra sheets, a supply of clean, old cloths, to be torn up as necessary, a flannel blanket to receive the baby in, six or eight napkins, a chamber vessel, a pair of sharp scissors, a paper of common pins, a paper each of large and small safety pins, a tumbler (not a goblet), and a teaspoon. She should also have at hand a complete suit for the child, a bottle of sweet oil, castile soap, soft wash-cloths, absorbent cotton, dusting powder, and a comb and brush. I always carry in my satchel a syringe, antiseptic tablets, and ligatures for tying the cord. These last are made by twisting together three strands of No. 16 cotton thread and doubling, and I find them better than tapes or silk, as they are strong and will not slip.

During labor the nurse should render what assistance she can, and when chloroform is used, as during the delivery of the head and in all obstetric operations, she should administer the anesthetic by means of an inhaler, under the direction of the physician. After the birth of the child, she should grasp the fundus of the womb through the abdominal wall, for the purpose of steadying it and assisting in the expulsion of the placenta, and subsequently preventing relaxation of the organ, with consequent hemorrhage. It is well that she keep the womb thus under control until the soiled cloths are removed and the bandage applied.

After delivery, the external genitals should be gently bathed with a hot antiseptic solution, and all blood removed from the thighs, perineum, and buttocks. In instrumental cases, or where the hand has been introduced into the womb, or we have any other cause to fear infection, an antiseptic intrauterine douche should be given. In other cases, in ordinary country practice, it is unnecessary. I do not advocate the routine use in private practice of injections during childbed, unless we have some positive indication calling for them. However, upon the first detection of any odor to the lochia, a vaginal douche of 1 to 5000 bichlorid, or a two-per-cent. creolin solution should be used as often as the urgency of the case seems to require. In maternities and thickly populated cities it is, no doubt, a proper precautionary measure to employ douches for five or six days following confinement, in every case. At present there seems to be some diversity of opinion as to the proper use of antiseptics in obstetrics; yet their employment in certain cases and under certain conditions has become well-nigh universal.

When labor is completed and the childbed toilet arranged, the woman should be given an opportunity for rest and sleep. If chilly, she should have a cup of hot coffee or milk, and be covered up well. A hot-water bottle should also be placed at her feet. All conversation with her and noise in the room should be interdicted. The child should be cared for in another room, and after the mother has slept, or at least rested, for half or three-quarters of an hour, it should be put to her breast, as the reflex stimulation of the womb thus excited will prevent the accumulation of intra-uterine clots.

It frequently happens that women, after childbirth, suffer from retention of urine. The nurse should bear this fact in mind, and not allow the patient to suffer pain from a distended bladder, while thinking her agony due to the inevitable after-pains. At intervals of about eight hours, unless contraindicated by some special condition, she should be lifted up in bed, and placed on a chamber vessel to urinate. By this means drainage from the womb and vagina is also secured. If retention ensues which is not relieved by hot cloths placed over the bladder, or by assuming the upright position, the catheter must be promptly passed.

The napkins should be made of sterilized gauze or absorbent cotton, and should be about four inches wide by twelve long. If cotton cloth or linen is used, it should be boiled, and afterward soaked in bichlorid solution and dried in a bake oven. The napkins should be prepared only as needed for use, and should be changed as often as they become much soiled. The bandage and bedding must also be changed as soon as soiled, and the discharges not allowed to dry on them.

If, when the milk appears, the breasts become over-distended and painful, part of the milk must be drawn away; otherwise, it may give rise to inflammation. Cracked or abraided nipples should receive immediate attention on account of the danger of infection. They should be gently washed with plain warm water before the child is put to the breast, and after nursing the milk and secretions from the child's mouth must be washed away with an antiseptic wash and an astringent dusting powder applied. Except in the mildest cases, a nipple shield should be employed, as it will hasten recovery and add to the comfort of the mother; but it must be kept scrupulously clean. Care must also be taken that the breasts are kept warm and not exposed to draughts of air, and if the milk leaks away soft cloths or absorbent cotton must be worn on the breasts and changed as often as they become wet.

In case of stillbirth, or when for any reason the child is unable to nurse, it will be necessary to stop the secretion of the milk. For this purpose the breasts should be well padded with cotton and a bandage applied smoothly and tightly. At intervals they should be bathed with a strong camphor solution, or belladonna liniment should be used under direction of the physician.

The duration of childbed varies in different cases. It should not be prolonged unnecessarily, yet it should cover the time of the most active involution of the womb, usually from seven to ten days. This rule should also be rigidly enforced in cases of abortion, at least after the second month. The bowels should be moved on the second day by enema or saline cathartic, and after that a movement secured every day. Much may be done to secure this by proper diet, which may include fruits, fresh meats and vegetables, oatmeal, prunes, and figs, but salt meats, milk and its compounds, pickles, pastry, cheese, and tea should be avoided.

In bathing and dressing the child, it is essential in the first place that the room be very warm. All draughts, as from swinging doors, must be studiously avoided. The nurse should begin by anointing the child with sweet oil or vaselin in order to dissolve the waxy material with which it is covered. After a few minutes she may begin washing it, first carefully cleaning the eyes, but using no soap to them on account of the irritation which it may produce. The water and wash cloth with which the body has been washed should never be allowed to touch the eyes, as infection might result. Subsequently, if the eyes become inflamed the fact should be promptly reported to the physician. In some States, and among them New York, failure to so report cases of inflamed eyes occurring during the first two weeks of life is a misdemeanor punishable by fine or imprisonment.

Probably the best treatment of the cord consists in washing it with bichlorid solution and dusting it with aristol or other antiseptic powder and enveloping it in a light layer of absorbent cotton. It should then be laid upward on the abdomen and a bandage applied, and not meddled with again, without just cause, for about five days. By that time it will generally come away, but no force is to be used to detach it.

The new-born child, in normal cases, does not need nourishment other than that it can get from the breast. It is a mistake to feed babies during the first few days, as it is not so intended by nature, and it is apt to give rise to colic. A babe frequently cries because its mouth is dry, hot, and uncomfortable, and it should be given water several times a day. It should also have water each time after nursing to rinse out the mouth. For the first day it should be put to the breast every hour; after that the interval should be lengthened. Ordinarily, if the child vomits or cries within a short time after nursing, it is evidence that it gets more than its stomach will hold comfortably, and it should be nursed less often or, better, not allowed as much at a nursing. If for any reason artificial feeding has to be resorted to later on, cow's milk should be diluted according to the age of the child, and sugar of milk and bicarbonate of soda added. Great care must be taken that the milk is not tainted in the least, and in hot weather, or where the milk has been transported some distance, it should be sterilized. The milk used should be taken from the mixed product of the whole dairy, and not from that of a single cow, as it will be less likely to vary from day to day. There is no prepared food manufactured which will take the place of cow's milk where the mother's milk is not available.

Frequently, the new-born babe will go for several hours, or even a day or more, without urinating; this will cause its parents much anxiety, but ordinarily no treatment is required. In such cases, nurses sometimes steep pumpkin seeds in water and give the decoction to the child, and this, they think, works like magic. The question of constipation in infants is too great to be considered in this place, and I would advise, in such cases, that the family physician be consulted and given entire direction of the child.

CLINICAL LECTURE.

PRACTICAL OBSERVATIONS ON THE CLASSIFICATION, ETIOLOGY, AND PATHOLOGY OF POSTERIOR DISPLACEMENT OF THE UTERUS.[1]

By JOHN M. FISHER, M.D.,
OF PHILADELPHIA;
CHIEF OF THE DEPARTMENT OF DISEASES OF WOMEN, AND DEMONSTATOR OF GYNECOLOGY IN THE JEFFERSON MEDICAL COLLEGE HOSPITAL; GYNECOLOGIST TO THE PHILADELPHIA HOSPITAL.

In order to fully comprehend the significance of abnormal deviations of the uterus it is of first importance to have a proper conception of the normal position of the organ. The uterus, as is well known, has no fixed normal position, but occupies its place in the pelvic cavity in a state of mobile equilibrium, with a constantly prevailing tendency, however, to an almost horizontal position anteroposteriorly; so that upon examinating a given subject in the erect posture, the bladder and rectum being empty, the fundus of the organ may be palpated immediately behind the symphysis, while the cervix forms a right angle with the vagina about two centimeters from the point of the sacrum. Your attention has already been drawn to the anatomy of the structures, and to the ever-changing position of the uterus consequent upon different bodily postures, varying degrees of intra-abdominal pressure, and the repletion and depletion of the rectum and bladder, the latter organ being particularly concerned in the production of physiologic retrodisplacements.

---

[1] A clinical lecture delivered at the Jefferson Medical College Hospital, February 23, 1897.

A uterine retrodisplacement, the result of a full bladder, for example, is physiologic because the organ returns to its former anteverted position immediately upon the evacuation of the vesical contents. A retrodisplacement, on the other hand, that remains uninfluenced by these extraneous forces is considered, not in all cases pathologic, but abnormal. Another matter of importance in the study of the normal position is that the uterus is slightly anteflexed at the junction of the body with the cervix, and at this point is possessed of a certain resiliency, or spring-like flexibility, which may be readily detected upon making a proper bimanual examination. This should be constantly borne in mind in order to appreciate the structural changes that frequently complicate abnormal displacements. The symptoms in the presence of anterior displacements are more frequently due to an associated metritis, with consequent rigidity of the organ at this point, than to the apparent version, or to the angle of flexion, and this obtains none the less in very many cases of retrodisplacements. The point I desire to make is that, while permanent anterior and posterior displacements of the uterus are abnormalities in themselves, anatomically considered, they frequently fail to constitute disease clinically. In support of this view I might urge a well founded additional reason, in that displacements of the uterus often exist without symptoms. To concisely formulate our observations bearing upon this subject thus far, we would say, therefore, that persistency of position, or stability of form, or both combined, are characteristics of abnormal displacements of the organ.

In no class of gynecologic disorders is a proper classification of so much importance to the practising physician as that of retrodisplacements of the uterus. Intelligently conceived, it at once becomes an index to both diagnosis and treatment. Unfortunately, great refinements of this subject have been introduced by different writers, that serve no practical purpose, but, on the contrary, have a tendency to confuse, rather than enlighten, the student in his search after useful knowledge. The classification, I shall give you, is easy of comprehension, and, to my mind, a most useful working formula at the bedside. Retrodisplacements, for practical purposes, should be considered—first, anatomically; second, etiologically; and third, clinically, as follows:

Anatomically—Retropositions, retroversions, retroflexions, retroversio-flexions, retroversions with anteflexion.

Etiologically—Congenital, puerile, acquired.

Clinically—Pathologic, complicating, indifferent.

The anatomic classification is of value for statistical purposes, and to express the exact position of the organ in language that cannot be mistaken. *Retroposition* of the uterus was discussed in detail at a former lecture, and will not be referred to again. *Retroversion* may be defined as a persistent posterior inclination of the uterus upon its transverse axis so that the fundus is in relation with the sacrum, while the cervix approaches the symphysis pubis. *Retroflexion* is a persistent posterior inclination of the body of the uterus, with coincident flexion upon its posterior face at its junction with the cervix. *Retroversio-flexion* is a retroversion, plus a retroflexion. This is the most frequent form of retrodisplacement of the uterus. *Retroversion with anteflexion* is a persistent posterior inclination of the uterus, with either coincident flexion upon its anterior face at the juction of the body with the cervix, or anterior flexion of the intermediate portion of the cervix.

The etiologic division of the subject is of special value, since the first thing to do in the treatment of any case, where this is possible, is to remove the cause of the disorder. A *congenital* retrodisplacement is one that has existed from birth. The term *puerile* is applied to cases that date their origin from the developmental period before puberty; and among the main factors operating upon the growing and pliable uterus in a deleterious way at this time are improprieties in dress and obstinate constipation—very important facts to bear in mind, when we come to consider the question of prophylaxis. By an *acquired* retrodisplacement we usually mean one that has occurred after the advent of puberty. Finally, to institute proper treatment in a given case, it becomes necessary to determine whether the displaced uterus in itself is really responsible for the prevailing symptoms, or whether the malposition is secondary to some more important pathologic lesion; hence, the clinical division. A *pathologic* retrodisplacement is one giving rise to symptoms that depend either upon the malposition itself or to diseased conditions, the result of the positional disorder. By a complicating displacement we understand that the displaced uterus is associated with, or constitutes a part of, pelvic disease of a more serious character than could be accounted for by the displacement itself. As distinguished from the two preceding, an indifferent retrodisplacement is one that is unattended by symptoms, whether the organ be movable or adherent. The latter condition may be likened to an ankylosed joint, the result and ultimate cure of a coxalgia. In the clinical sense, neither constitute disease, and I may state, in passing, the indication in the one is equally applicable to the other, and that is to "leave well enough alone."

Faulty obstetrics and improper care of the puerperal woman are responsible for the vast majority of retrodisplacements of the uterus. In a subject of ordinary development, after the completion of the third stage of a properly conducted labor, the contracted uterus is generally seen bulging the lower abdomen, and may be felt as a round, hard body, reaching about four or five inches above the level of the symphysis. Within one week the involution process has reduced the organ in weight from two and two-fifths pounds to one pound, and by the tenth day it is usually so much reduced in size that the fundus only slightly overtops the pubis.

Very commonly, after delivery, the patient is directed to remain lying on her back, the accoucheur applies an abdominal binder that is tightened from time to time for a period extending over ten days or two weeks; the patient's bowels are often confined for three or four days at a time, and the bladder is still more frequently allowed to go for twenty-four hours, or even longer, without being emptied of its contents. Think for a moment, and you cannot but appreciate the pernicious influences that such forces must have upon a recently emptied uterus, inclining as it does, with the greatest freedom, to one or the other side with the changing position of the patient.

Retrodisplacement early in the puerperium cannot occur, because the uterus, at this time, is too large to pass the promontory and accommodate itself to the hollow of the sacrum; but as involution progresses, say after the lapse of three or four days, you can readily test the facility with which posterior version may be accomplished by simply depressing the organ with one hand over the abdomen, while the cervix is tilted forward into the axis of the vagina with the other. Once the fundus has passed the promontory and the intra-abdominal pressure is brought to bear on its anterior face, retroversion exists, and unless corrected before involution of its supports adapts these to the new position of the organ, it is sure to remain permanent. A tightly applied binder, or a full bladder, or both together, acting upon the body of the puerperal uterus, with, in many cases, the additional force of a distended rectum pressing the cervix forward at a time when retroversion is possible, may, and often do, accomplish precisely the same thing.

The process of involution referred to is not confined to the uterus and its appendages, but applies to its ligaments, in fact to all of its direct and supplementary supports, including the vagina and the perineum, and, though rapid at first, requires seven to eight weeks for its final completion. This retrogressive change, however, may fail, or, after having reached a certain stage, may be arrested, owing to the supervention of certain local diseased conditions, or some constitutional state favorable to the production of subinvolution. This may obtain with reference to one or several of these structures, or all of them combined, and whenever it does occur is almost certain to result in a displacement of one or more of the generative organs, frequently involving either the rectum or bladder, or both together.

A subinvoluted uterus, by its increased weight, makes extraordinary and very often impossible demands upon the integrity of othewise efficient ligaments. Owing to want of necessary support it descends from its normal level in the pelvis, the cervix seeks the axis of the vagina to escape resistance from behind, while the other end of the uterine pole is tilted backward, so that the intra-abdominal pressure previously directed against the posterior face of the body of the organ now in turn impinges upon the fundus and anterior surface, thus still further increasing the displacement, and accordingly as the uterine wall is rigid or softened will the displacement remain a version, or have superadded a condition of flexion. If, in addition to the enlarged state of the organ, the ligaments are likewise in a state of subinvolution, or the vagina and perineum continue softened and relaxed, you can readily understand how these structures by the loss of function constitute contributing elements in the production of retrodisplacements, or how they permit a displacement to take place, in the presence even of a normally involuted uterus.

In our study of this subject it is well to bear in mind that a retrodisplacement of the uterus may be due primarily to what we term sectional subinvolution. The anterior wall of the organ, whenever this has been the site of placental attachment, may be thus affected, while involution progresses normally throughout the rest of its structure, thus leading to a comparative shortening of the posterior segment with resulting backward flexion of the body upon the cervix. These respective conditions may likewise obtain with reference to the transverse division of the organ into body and cervix, involution of the former taking place, while the process at some stage may be arrested in the latter, or *vice versa;* in either case the uterus is heavier than normal, and is therefore liable to undergo descensus and posterior version.

Among the most frequent causes of retrodisplacements of the uterus referable to the puerperal state are lateral rupture, muscular diastasis, and overstretching of the pelvic floor. The primary effect of any one of these accidents is loss of function on the part of the levator ani muscle. This muscle, covered by its fascia, as you well know, enters very largely into the formation of the pelvic diaphragm, and thus acts as a means of supplementary support to all the upper pelvic organs. It is directly concerned in maintaining a closed condition of the vagina, preventing prolapse of its walls, and by its attachment to the lower bowel preserves the sigmoid curve of the rectum, holds the anus at a proper level, and performs the very important function of making counter pressure during defecation. The straining efforts incident to an evacuation of the rectum, especially in the presence of constipation, causes descent of the uterus with a tendency to retroversion, until arrested by the resisting fibers of the levator ani, while subsequent muscular contraction of the uterosacral ligaments is the chief factor in restoring the uterus to its previously anteverted position upon the completion of the act. Whenever the levator ani has been ruptured or is relaxed, therefore, it causes relaxation, and in most cases gaping, of the vagina; the gluteal cleft becomes more or less obliterated by a dropping of the anus and rectum to a lower level, so that defecation subsequently is accomplished solely at the expense of intra-abdominal effort, and prolapse of the uterus and its appendages, as well as that of neighboring organs, either separately or conjointly, is apt to follow. Permanent backward displacement of the uterus under such circumstances occurs in consequence of the increased latitude for downward displacement, leading to overstretching, exhaustion, and finally atrophy of the muscular structure of the uterosacral ligaments.

In our study of posterior displacements of the puerperal uterus it must now be clear to you that one of the four following conditions, or two or more acting together, are responsible for the great majority of these malpositions, *viz.:* First, increased weight of the uterus; second, softening of the uterine walls; third, increased intra-abdominal and faulty extra-abdominal pressure; fourth, loss of support. All posterior displacements, however, do not originate in the puerperal state. Increased weight and softening of the uterus may be caused by inflammatory changes other than those liable to follow a confinement, or may occur as a result of new growths in its walls, and thus cause displacements that give rise either to special symptoms, or aggravate the original disease, or, on the other hand, act the part simply of indifferent complications. Increased intra-abdominal pressure, the result of violent bodily jars or falls, may cause a sudden acute retroversion of the uterus, a condition attended with most distressing symptoms. The wearing of tightly laced corsets, and of heavy skirts suspended from the waist, primarily depress the uterus so that the cervix seeks the axis of the vagina, and by a change of the intra-abdominal forces in their relation with the body of the organ, it finally becomes retroverted or retroflexed. Chronic constipation, even by the action of the distended rectum upon the vaginal portion of the cervix, and the necessarily increased intra-abdominal effort during defecation, is likewise a potent factor in the causation of retrodisplacements. Any organic pelvic disease outside of the uterus may involve the organ in a displacement either by acting upon it directly or secondarily through the intervention of the circulatory, lymphatic, or nervous apparatus, thus effecting structural changes in the organ or its supports favorable to the production of a malposition.

A permanent retrodisplacement of a uterus otherwise normal, I repeat, is, anatomically considered, abnormal, because the former physiologic variations of position no longer obtain. It may become diseased because with the displacement of the uterus there is more or less displacement of ovaries and tubes and torsion of its lateral supports, the former, under these circumstances, being exposed to irritation from pressure involving the uterus; secondarily, while the distorted condition of the latter may offer a barrier to the return circulation, which, in many cases, is intensified by contact of these structures with the uterosacral ligaments, resulting in venous tension and enlargement of the organ, with consequent softening and infiltration of its structure. This may be still further aggravated by a bend in the uterine wall, thus, at the same time, contributing an additional source of irritation in a retention of uterine secretion above the point of flexion. In the presence of endometritis and metritis—necessary sequelæ of these pathologic changes — it is easy to conceive an extension of the disease process to the ultimate development of salpingitis, with tubal leakage, and the retinue of evils attending the various forms of pelvic inflammation, so that the uterus, though, in a certain sense, primarily at fault, may eventually play the part merely of an epiphenomenon engrafted upon more important pathologic lesions.

The Popularity of Lord Lister.—The *Medical Press* affirms that it is no more than the truth to say that at the present time Lord Lister is, from a public point of view, one of the most interesting members of the House of Lords. His personality has become a very popular one; everywhere those who formerly had scarcely heard of his fame have now learned the reason of the gratitude which humanity owes to him.

CLINICAL MEMORANDA.

A CASE OF HYSTERECTOMY FOR SEPTIC PUERPERAL METRITIS.[1]

BY JOHN OSBORN POLAK, M.D.,
OF BROOKLYN.

SUCCESSFUL hysterectomy for septic metritis during the puerperium is of sufficiently rare occurrence to warrant the record of this case.

Agnes S., aged thirty-three, born in Poland, was admitted to my service at the Eastern District Hospital, Brooklyn, January 14, 1897. She had had four children and three miscarriages. The last pregnancy resulted in a still-birth at term, four weeks previous to her admission. She was attended by a midwife in this labor, and fever followed. Her condition became so alarming after twenty-three days of septic toxemia that application was made for her admission to the hospital. Rigors had occurred several times each day.

Her general appearance was that of toxic anemia with emaciation, so characteristic in sepsis. There was dulness over the base of the left lung, with well-marked bronchial breathing over the same area. The sputum was mucopurulent, but did not contain Koch's bacilli. The abdomen was distended and tympanitic, with marked tenderness over the pelvic region, especially in the left iliac fossa. The fundus uteri could be palpated above the pubes for a distance of 3 cm. The pelvic floor was found to be torn in the median line, involving a few of the anterior fibers of the anal sphincter. The uterus was enlarged and fixed slightly back of the normal position by induration in each broad ligament. A thick, purulent discharge issued from the cervix, which was enlarged, softened, and lacerated bilaterally. The os was patulous and there was a marked ectropion of the cervical mucous membrane. The adnexa could not be satisfactorily palpated. Constant vomiting of grumous material accompanied by epigastric pain added gravity to the case. The evening temperature reached 102° F. with morning remissions, while the pulse was weak and fluctuated between 120 and 140 beats per minute.

The treatment was suppurative and stimulating with vaginal and intra-uterine irrigations of permanganate of potash solution. No benefit resulted, and after consultation hysterectomy was performed by the vaginal route on January 23, 1897. During the preliminary curettage the uterus was punctured anteriorly just above the internal os, the curette being distinctly appreciated in the uterovesical fold by the abdominal hand. Ligation of the uterine arteries was attempted, but abandoned because of the friability of the tissues. Hemastasis was obtained by the use of large clamps, the cervix was amputated, and the fundus retroverted through the posterior vaginal incision. This last step in the technic presented difficulties, owing to intraligamentous thickening and corporeal enlargement. Both ovaries were cystic, the cysts rupturing during the enucleation. The extreme vascularity of the parts greatly complicated the ablation, but the operation was completed in thirty-two minutes, the patient being in fair condition.

---

[1] Read before the Obstetrical and Gynecological Section of the New York Academy of Medicine, March 24, 1897.

The temperature succeeding operation remained high for several days, reaching 104° F. on the fifth day. The clamps were removed in forty-eight hours. The intrapelvic gauze was allowed to remain *in situ* for five days, when it was withdrawn, the cavity irrigated and lightly repacked, after which the temperature fell to normal and the convalescence was uninterrupted. During the first twenty-four hours but one and one-half ounces of urine was secreted; suppression, though not in so extreme a degree, continued for the first week, during which time nitroglycerin and colon infusions of normal salt solution were very freely exhibited.

What I considered most remarkable was the fact that the infection had spread directly from the uterus into the broad ligaments through the lymphatics, while no involvement of the tubes had occurred after four weeks of sepsis. In my opinion the case illustrates the possibility of the occurrence of intraligamentous cellulitis from direct uterine extension, and demonstrates that occasionally the tubes play no part in pelvic inflammation.

REPORT OF THREE CASES OF GRAND HYSTERIA.

BY J. STEWART DOUBLEDAY, M.D.,
OF NEW YORK.

CASE I.—A. B., aged twenty-two, a law student, first came under my observation several months ago. He was a man of high intellectual gifts, was strong physically, and considerable of an athlete. There was a history of insanity in his family, and the knowledge of this fact weighed greatly on his mind, particularly as he felt that his own nervous failing was of a progressive nature. He was in constant dread that his trouble would ultimately lead to his confinement in an asylum. His attacks of hysteria were very peculiar, and although occurring irrespective of the ingestion of alcohol, the drinking of a glass of beer, or of a small amount of sherry wine, would be sufficient to induce an attack. The seizure could not in any way be confounded with one of delirium tremens. There would be great merriment, and his speech, usually of the most refined order, would become vulgar and profane. The exhilaration of spirits would be followed by a quarrelsome and delirious condition during which he looked upon every person as an enemy. Then he would become violent and it required several men to hold him. He would shout, scream, and groan. Semi-intentional clonic convulsions would occur in which the teeth were ground together. The pupils would strongly contract, and afterward become widely dilated. He complained at this stage of great pain, but was unable to locate it. At no time during an attack was the tongue bitten, nor was incontinence of urine or feces present. A condition of semi-coma followed the excited stage, which a cold douche speedily relieved. This was usually followed by vomiting. When relaxation was complete a large quantity of colorless urine was passed. During the attack the pulse-tension was high, but afterward it was low, and the temperature subnormal. No abnormal condition of any organ could be made out.

CASE II.—This was the case of a girl eighteen years old whom I saw at the Orange Memorial Hospital. She had been under treatment for some time for chlorosis, and when I saw her the hemoglobin percentage had risen from forty to eighty-five. The attacks of hysteria had decreased in number at first but afterward became more frequent, in spite of the fact that her general condition had greatly improved, and averaged about one a day. During the seizure, which usually occurred just after she had received some attention from the physician in charge, or when she had been especially noticed, she would moan at first for two or three minutes, then scream, and would apparently lose consciousness, the face becoming very pale, the pupils extremely dilated, or unequal, and the head rolling from side to side. The trunk, and upper and lower extremities would at first show a tonically convulsed condition, and irregularly choreic movements, and this would be followed by a very fine tremor of the whole body. Consciousness was restored without any intervening period of apparent coma. Very often she would "wake" only to have an immediate repetition of the attack. If she was left entirely alone the seizure ceased much sooner than when her condition seemed to cause anxiety or debate among those around. When the attack was over the usual "hysterical urine" was voided in very large amount. During the seizure nothing that was attempted seemed to exert any beneficial effect. The patient appeared to be totally unconscious and even when touched with the actual cautery, pricked with a needle, or when a slight incision was made (each of which was tried more than once) there would be no sensation of pain, at least so far as we could determine from movement, expression, or question. One day, by way of experiment, when the patient appeared to be truly unconscious and was undergoing clonic convulsions, with the widely dilated pupils above referred to, I took her hand and told her in a firm voice that if she did not get better of her infirmity she could never get married. The effect was immediate. A slight smile appeared at the corners of her mouth, the convulsions ceased, the pupils and expression became normal, and she was entirely conscious. I used this method twice with excellent effect. The therapeutic suggestion was one which Dr. Weir Mitchell had used in the case of a young woman engaged to be married and who was affected with intractable hysterical vomiting. In his case, however, there was consciousness.

CASE III.—I saw this case a week ago in private practice. The patient is a laundress, a young woman of twenty-five. She has suffered for three or four years from *grande hystérie*, the attacks coming on at the menstrual period. She has some dysmenorrhea, but in every other way is in good health, and is physically very strong. At no other time is she affected, and between the periods has no trouble whatever. The attacks are somewhat peculiar in being always preceded by a condition of malaise, which lasts for twelve hours, during which period the patient complains of pain which she cannot locate, and moans incessantly. This is followed by howling and screaming, apparent unconsciousness, and tonic, clonic, and tremulous conditions. In this case the eyes are always tightly closed.

I have now seen twelve cases of this disease, all but one of the patients being women, and I have always been impressed with the fact that the facies accompanying the condition is peculiar. It is very different from that met with in epilepsy, mania, or neurasthenia. The face is decidedly oval in shape, the chin is large but weak, the lips are heavy, the eyes are slow in movement, the brow is narrow, and the cheek bones are large. There is always a decided suggestion of sensuality in the expression.

During the attack the immediate employment of the hot and cold bath is to be highly recommended. The patient should be kept in each for two minutes, and then allowed to rest in warm or tepid water till complete relaxation obtains; she should then be put to bed and have perfect quiet. If the baths are not at hand, hot and cold douches are to be employed. Stimulants should be given only when needed. Vomiting usually occurs at this stage. If it does not occur it is well to induce it with a nauseous dose of oil, salt, or warm water. Afterward sulphate of magnesia should be given in one full dose. The curative treatment is too lengthy a matter to treat of here.

AN ANALYSIS OF 114 CASES OF MASTOID INVOLVEMENT COMPLICATING ACUTE MIDDLE EAR SUPPURATION.[1]

By J. E. SHEPPARD, M.D.,
OF BROOKLYN, N. Y.;
PROFESSOR OF OTOLOGY AT THE LONG ISLAND COLLEGE HOSPITAL MEDICAL SCHOOL, BROOKLYN, AND AT THE NEW YORK POLYCLINIC; AURAL SURGEON TO THE BROOKLYN EYE AND EAR HOSPITAL.

I WISH in the first place to emphasize the fact that this article refers *only* to such cases of mastoid trouble as have accompanied *acute* middle ear suppuration, and does not include those not infrequent cases which run their course *without* suppuration in the tympanic cavity, nor the *chronic* suppurations.

Symptomatology.—Discharge from the ear in all of the 114 cases; pain (spontaneous) in 102; tenderness, either of the whole or some portion of the mastoid, most frequently the apex, in 101; posterior superior perforation of the membrana tympani in 52, of which 17 were distinctly pouting or teat-like; tinnitus of all kinds 56, of which 44 were described by the patients as being pulsating in character, the terms used by them being "puffing," "blowing," "beating," "hammering," etc.; drooping or bulging of the posterior superior canal wall into the lumen of the canal in 36, in 12 of which it was bulged so much as to entirely obstruct a view of the membrane. There was swelling over the mastoid, with or without a pushing of the auricle out from the side of the head, in 22 cases, in nearly all of which the swelling was present when I first saw them.

Etiology.—All the information that could be gained on this point is here shown:

"Colds," "colds in the head," "colds in the throat," etc.	24
"Sitting in a draught"	1
"Washing the head"	1
"Sea-bathing"	4

The following table shows the diagnosis made in the different cases, together with the complications met with:

Acute middle ear suppuration, mastoiditis (uncomplicated)	76
Acute middle ear suppuration, mastoiditis, Bezold form	3
Acute middle ear suppuration, mastoiditis, secondary periostitis	19
Acute middle ear suppuration, mastoiditis, secondary periostitis, suboccipital abscess	1
Acute middle ear suppuration, mastoiditis, "mixed" middle and internal ear disease	2
Acute middle ear suppuration, mastoiditis, furuncle of canal	1
Acute middle ear suppuration, mastoiditis, erysipelas	3
Acute middle ear suppuration, mastoiditis, diabetes	3
Acute middle ear suppuration, mastoiditis, diabetes, erysipelas, and meningitis	1
Acute middle ear suppuration, mastoiditis, meningitis	2
Acute middle ear suppuration, mastoiditis, meningitis and cerebral abscess	1
Acute middle ear suppuration, swollen tender glands in the region of mastoid apex	2
Total	114

Out of the whole number of cases the result is unknown in	25
Recovery took place without operation in	26
Recovery (both ears affected) without operation in	8
Operation followed by recovery in	46
Operation (both ears) followed by recovery in	4
Total number of deaths	5
Total	114

The following details may not be out of place concerning the five patients that died:

CASE VIII.—I first saw this patient in consultation and recommended that antiphlogistic measures be carried out for forty-eight hours, when, unless the symptoms were greatly improved, the mastoid should be opened. Nothing further was heard from the case for six days, when the patient had well-marked meningitis, together with evidences of a secondary periostitis. To relieve tension an incision was made through the periosteum, but the disease had progressed too far during the delay to think of saving the patient's life.

---

[1] Read before the American Otological Society at New London, July 14, 1896.

Case XVII.—I saw this man but once, in consultation, about three hours before his death, when operation was quite out of the question. It was an unrecognized mastoiditis, infection taking place through the inner mastoid table, with the development of a cerebral abscess, which was also unrecognized, and later meningitis.

Case XXXI.—This patient was a diabetic; he had an ordinary case of mastoiditis, which was operated upon, and he was apparently making a good recovery, when a violent attack of erysipelas supervened, followed shortly by meningitis and death.

Case LXXXIX.—This was another case of partial recovery after opening the mastoid, the patient having done perfectly well for ten days, when, owing to unfavorable surroundings, she too developed facial erysipelas, for which it was necessary to remove her from my care to the Flatbush Hospital, where she afterward died.

Case XCVI.—In this case the mastoid symptoms came on with great violence as an accompaniment of a recurrent middle ear suppuration. The mastoid was opened just three and a half days after the onset of the middle ear inflammation, death from meningitis taking place three and a half days later. The intracranial inflammation must have started very soon after that in the ear to have run such a rapid course, and the question arises in my mind whether this may have been one of those exceptional cases with a bony hiatus in the roof, either of the tympanic cavity or the mastoid antrum. Unfortunately, an autopsy was not allowed.

A summary of the cases is as follows: (1) For opening the mastoid the gouge or chisel has been invariably used, excepting only those cases in which the cortex was so much softened as to make the sharp curette more applicable. (2) For clearing out the mastoid, sharp curettes were used for the outer, blunt curettes for the deeper, portion. (3) *Grippe*, outside of the acute affections of the nose and nasopharynx due to cold, etc., has played the most important rôle in the the etiology. (4) The symptoms are important in about the following order: (*a*) pain, either in the mastoid or in some part of the affected half of the head; (*b*) tenderness, either of the whole or of some part of the mastoid (oftenest of the apex); (*c*) drooping, or bulging, of the posterior superior canal wall into the lumen of the canal, especially if this is near the membrane; (*d*) posterior superior perforation of the membrane, especially if pouting or teat-like; (*e*) pulsating tinnitus, when it continues as a marked symptom after the time it should have ceased, were the case one of simple middle ear inflammation; (*f*) the external symptoms—redness and edema of the mastoid, and pushing outward of the auricle. (5) Abortive measures should be employed in a majority of cases for from two to five days, and will, as my cases show, be successful in curing a fair proportion of all cases. Having failed to give relief after the judicious use of abortive treatment, I believe the following may be justly given as the remainder of my conclusions: (6) We must time and again operate on the strength of one or two symptoms, and often with even these only slightly marked. (7) If a patient is seen before the external manifestations of mastoiditis have developed, we should never wait for their appearance, because by so doing we give the pus the same opportunity for breaking through the internal, as through the external mastoid cortex, the patient's life being meantime jeopardized to just that extent. (8) The operation, if performed with due care, is relatively free from danger. Danger to the patient arises, not from the operation, but from delay in performing it. (9) Finally, my cases make me believe that a pretty safe general rule would be, *when in doubt, operate*.

The following cases will, perhaps, demonstrate some of the difficulties of diagnosis and a few of the unusual complications met with, and at the same time make clear the dangers that would have accrued from waiting for the development of the external symptoms of mastoiditis.

Case VII.—Acute middle ear suppuration; mastoiditis; operation; recovery. Indications for operation: Severe pain, slight pulsating tinnitus, very slight tenderness. These seemed to me very slight indications, and yet the whole mastoid was found to be gutted out into one enormous cavity, and the inner mastoid cortex had entirely disappeared over a space as large as a 25-cent piece. On probing over this area, the membrane was so much softened that the probe, almost of its own weight, penetrated the lateral sinus, resulting in the escape of a large amount of dark, grumous blood. The hemorrhage, however, was easily controlled by pressure. The patient had a chill on the fourth day, after which recovery was uninterrupted.

Case XXV.—Eczema of the external auditory canal; acute middle ear suppuration; mastoiditis; operation; recovery. Indications for operation: Long-continued, profuse discharge, with a suspicion of mastoid tenderness. This case was first treated for eczema of the canal, without perforation; then perforation occurred, as I always thought, from without inward; later, an acute middle ear suppuration developed, all the symptoms of which subsided, excepting that a very profuse discharge continued. Finally, after waiting a full month for the discharge to cease, and with this and the slightest suspicion of mastoid tenderness as the only indications, I operated and found a large quantity of pus and a very necrotic mastoid. From this time the patient recovered rapidly.

Case LXVI.—Acute middle ear suppuration; mastoiditis; operation; recovery. Indications for operation: Pain, tenderness, and drooping of the posterior superior canal-wall. This case is peculiar in its apparent etiology. The patient's ear was syringed for impacted cerumen, whether violently or not I do not know, after which for two days there was much relief; then the ear commenced to pain violently, followed after two days by a discharge, which, with the pain, continued until I saw him two weeks later. At this time there was marked mastoid tenderness, with decided bulging of the posterior superior canal wall, which, with the continued pain, were sufficient in my judgment to indicate operation, which was performed at once, showing much pus and granulation tissue in the mastoid cells. Whether or not the mastoiditis bears to the syringing of the ear for cerumen the relation of effect to cause, I do not know, but careful inquiry failed to elicit anything else as a probable cause.

CASE LXXIV.—Acute middle ear suppuration; mastoiditis; operation; erysipelas; recovery. Indications for operation: Pain, tenderness, pulsating tinnitus, beginning drooping of posterior superior canal wall, and posterior superior teat-like perforation. This case was, to me, unusual, in that it was the first in the negro race on which I had been obliged to operate in this way. The mastoid cortex and the apex were about as in most cases. Above the apex, and considerably posterior to the bulge of the inner cortex marking the location of the sinus, was quite a large cavity (one-half inch deep) filled with granulation tissue and pus. In front of the sinus prominence there was but little space through which to get to the antrum, and while working in this direction the sinus wall was exposed for a space about one-third of an inch square. Finally, the posterior wall of the bony canal had to be chiseled away, after which a very small antrum was found, filled with granulation tissue. Another complication, due to the black skin of the patient, and new to me, was the difficulty in determining during the first two days what the attack was, which later proved to be erysipelas.

CASE XC.—Acute middle ear suppuration; mastoiditis, Bezold form; operation; recovery. Indications for operation: Pain, tender swelling below the mastoid apex, loud beating tinnitus, and marked drooping of the posterior superior canal-wall. This man, when I first saw him, had a large, red, hard, board-like swelling extending from the mastoid apex downward two and one-half to three inches under (internal to) the sternomastoid muscle. The mastoid was opened and cleared out. A perforation of the tip was found, and through this a probe was passed under the sternomastoid coming to the surface along its posterior border. Using this as a guide to cut down upon, a counter opening was made, and a drainage tube passed through the perforation at the mastoid apex, under the muscle, and brought out through the lower opening. The swelling did not extend any further downward, and the patient rapidly recovered.

CASE CIV.—Acute middle ear suppuration; mastoiditis; operation; recovery. Indications: Pulsating tinnitus (very annoying), tenderness, not of, but posterior to, the mastoid, and a numb feeling of the affected half of the head. This case was in a nursing mother, and at first seemed an inflammation of the tympanic cavity only, with every evidence of recovering; after about two weeks, however, she commenced to complain of a very annoying "beating" tinnitus, the discharge continuing. Later, tenderness appeared, but was never more than slight, and was always localized posterior to the mastoid process. The next symptom of which the patient complained was a numb feeling of the affected half of the head. Pain was never present to any considerable extent. Operation showed about half a dram of pus in a cavity running back between the tables of the skull into the occipital bone. Recovery uneventful.

CASE CVIII.—Otitis externa hemorrhagica; acute middle ear suppuration; mastoiditis; operation; recovery. Indications: Pain in the parietal region, pulsating tinnitus (very troublesome), and tenderness immediately below the auricle. When first seen the canal was entirely blocked by two large hemorrhagic extravasations on opposite walls. These were punctured, and the membrane seen not to be perforated, though much inflamed, a small perforation appearing later. The pulsating tinnitus, which was one of his first symptoms, continued until after the operation, six weeks from the time I first saw the patient, and that, with an obscure, not very severe, pain high up in the parietal region, was about the only evidence of continuing trouble until a few days before I operated, when marked tenderness appeared close under the auricle in front of the mastoid. Finally, with much doubt as to the findings, operation was undertaken. The superficial cells, the cells toward the antrum, and those toward the apex, were normal, and I was beginning to think that I had for the first time opened a mastoid unnecessarily when, on going further inward and downward in the apex region than I had ever done before, apparently internal to the digastric groove, about a dram of pus was found. After this recovery was uneventful.

CASE CXIII.—Acute middle ear suppuration; mastoiditis; operation; recovery. Indications: Tenderness, pulsating tinnitus, drooping of the posterior superior canal wall, and posterior superior pouting perforation. The two or three points worthy of mention are, (1) the tenderness, which was only moderate, and was located very far posteriorly, the apex and body of the mastoid being entirely free from it; (2) the pain during the four weeks previous to the time the patient came to me had almost entirely subsided, yet in spite of his slight symptoms, the pus cavity in the mastoid was found to be in direct contact with the wall of the lateral sinus over a space half as large as a 25-cent piece. Recovery was unusually rapid.

MEDICAL PROGRESS.

Post-Febrile Insanity.—HODGDON (*Maryland Med. Jour.*, March 27, 1897) does not take as gloomy a view of the prognosis of post-febrile insanity as do most alienists. He has found that full sedative doses of bromid of soda, if given in conjunction with tonic treatment, nourishment, and stimulants as soon as the earliest symptoms appear will succeed in most cases. If the patient can afford both a day and a night attendant, he is much better off outside of an asylum than in one.

Disinfection of Books in Circulating Libraries.—Owing to the possibility of infection by means of books obtained from circulating libraries, numerous attempts have been made to find some cheap, quick, and satisfactory method for their disinfection. The latest of these attempts is described by SCHAB in the *Centralblatt f. Bacteriologie*, February 6, 1897. His experiments were made upon books infected with pyocyaneus, staphylococcus, aurus, anthrax, and tubercle. As disinfectants, sulphurous acid gas and formaldehyde were employed. The sulphurous acid gas was able to kill pyocyaneus in twenty-four hours. The other bacteria, in many instances, were not affected by exposures of forty-eight hours, even when the books were previously moistened. Results with formaldehyde were even less satisfactory. It is evident that books, because of the close contact of their leaves, which are often made of a glazed paper, offer a great resistance to the penetration of gases, and must ever remain among the most difficult of all objects to sterilize.

General Therapeutics of Infectious Diseases.—ROBIN (*Bull. Gen. de Therapeutique*, February, 1897) finds, in infectious diseases, that the toxins diminish the power of the red blood cells to carry oxygen. Thus the power of oxidizing the waste materials and bacterial products is lessened. The kidneys and other emunctory organs are also rendered less capable of performing their functions, so that there occurs an increase in the solids, toxins, waste materials, etc., of the blood and a diminution in the solids, urea, and other products of oxidation eliminated in the urine.

In febrile affections, typhoid, for example, the gravity of the disease is in proportion to the amount of unoxidized materials in the blood, and is indicated by a decrease in the urinary solids. Thus the chemical examination of the urine is a valuable means of making a prognosis. Even when the general symptoms are favorable, if on examination the urine is found to contain a marked decrease in the solids, the condition may be considered serious, and *vice versa*.

A New Method of Obtaining Urine from a Single Kidney.—In the *Centralblatt f. Gynakologie*, February 6, 1897, ROSE describes a method of obtaining urine from a single kidney. In order to accomplish this purpose, which is often of great importance diagnostically, various measures have been proposed. Pressure upon one ureter, either bimanually or through the vagina, or by means of a special clamp, is an uncertain procedure. HEGAR proposed to cut down upon the ureter through the vagina and stop for a time its flow of urine. This method is certain, but is in itself an operation. By means of the cystoscope it is sometimes possible to determine that the urine from one ureter contains pus or blood, while that from the other is clear. At times this distinction is made with difficulty, or not at all, and in the most favorable cases no information is gained as to the chemic or microscopic condition of the urine. The catheterization, as proposed by Nitze and Kelly, requires considerable practice, expensive apparatus, and often an unpleasant dilation of the urethra. Rose's procedure is based upon the fact that the bladder of a woman in the knee-chest position, or with the pelvis elevated in the dorsal position, will distend with air if a speculum is introduced through the urethra. Through this speculum it is possible to see by direct or reflected light the openings of the ureters; and if the speculum is cut obliquely, its inner extremity; it may be clamped over one ureter, while the urine from the other ureter flows down over the posterior bladder wall toward the umbilicus. When sufficient urine for examination has collected in the speculum it can be drawn into a syringe, the speculum be withdrawn and cleansed, the bladder irrigated, emptied, and again distended with air, and the speculum placed over the mouth of the ureter of the opposite side. In cases of extreme sensitiveness the use of cocain is recommended. As the urethra is not dilated, narcosis is unnecessary, and a resulting incontinence of urine is not to be feared.

Relations of Nervous Disorders in Women to Pelvic Disease.—WIER MITCHELL (*University Magazine*, March, 1897), while admitting that nervous diseases in women brought about by abnormal conditions of the pelvic organs are often cured by surgical measures, still warns against too great a reliance upon surgery alone. A great many aggravated cases of hysteria have disease of the pelvic organs, which is so apparent as to make recovery by the removal of the ovaries and tubes seem probable. A large percentage of these cases are not made better by operation, but, on the contrary, often made much worse, or else gain nothing on the side of the neurosis. Hysteria is not a disease of sex, and it is not often cured by oophorectomy alone, even if justified by physical disease. The success of a surgical operation would be far greater if the women had prolonged preparative rest treatment. Usually a year passes after operations of the nature under discussion before full health can be expected.

The writer is inclined to think that post-operative traumatic insanities are the more common after pelvic operations than after others. It is apparently sometimes due to the anesthetic, since twice in his knowledge it has followed operations of a trivial nature.

A Case of Sudden Decoloration of the Hair.—FÉRÉ relates in *La Progrès Médicale*, January 23, 1897, a case of partial canities occurring very rapidly. The possibility that the hair should suddenly turn white has been denied on physiologic grounds by some dermatologists, notably Kaposi, but it is, nevertheless, supported by numerous well-authenticated instances. The case which came under Féré's observation was that of Mrs. B., who was at one time treated by Charcot. At that time she experienced after the lightest repast intense pain and a revulsion at the idea of food. She became extremely emaciated, the skin became dry, and the extremities cold and senseless. There were also disturbed sensation and various other phenomena. Forced to take nourishment through a tube these symptoms rapidly disappeared, and in a short time she was perfectly well.

She married and had four children. Four years after the birth of the last child she stopped one day in the middle of the street, while on the way home, believing she had forgotten something. Suddenly perceiving a stage coming toward her—though not near enough to place her in any danger—she rushed into the nearest house and fell into a chair in a state of extreme agitation. Having recovered a little of her self-control, she returned home and slept well that night. The following day she merely noticed that her menstrual pain (for this happened during her catamenial period) was greater than usual. On the next day—*i.e.*, the second after the accident—she observed that a lock of hair on the right side of her head had lost its color. The hairs were totally decolorized throughout their whole length; otherwise they were unchanged in character. The area from which they sprang measured eighteen by twenty-two millimeters. The skin was not hypersensitive or in any way abnormal, except that in its center there was a small V-shaped scar, which was not painful, and was not adherent to the skull. The rest of the hair had its usual brown color.

So-called Spider Bites.—DAVIDSON, in an article on this subject printed in the *Therapeutic Gazette*, February 15, 1897, expresses the opinion that many of the infectious bites attributed to spiders are not caused by these insects. Several naturalists have allowed themselves to be bitten by the largest poisonous spiders without serious result. It is doubtless true that, nevertheless, certain people are especially susceptible to spider bites as they are to bee stings. Some people have died of collapse half an hour after the receipt of a bee sting.

Many of the cases of so-called spider bites are thought by Davidson to be caused by the pirate bug (*Rhasahus Biguttatus*, Say). The bite of this insect is usually followed by local cellulitis with a central dark spot around which there frequently develops a bullous vesicle about the size of a 10-cent piece and filled with a dark grumous fluid. In a few days, with rest and under the application of wet antiseptic dressings, the cellulitis resolves.

THERAPEUTIC NOTES.

Peronin for Cough in Phthisis.—SCHROEDER extols in the February number of the *Therap. Monatshefte* the virtues of Peronin to quiet the cough in phthisis. He administered it for a considerable time to twelve patients in doses the same as those of codein phosphate with which it was compared. The plan was to administer the peronin in gradually increasing doses, beginning with the third of a grain and increasing up to twice that quantity. In eight cases the irritation from the cough was at once relieved. In two it was relieved with larger doses only, while two patients were not benefited at all. On the character and amount of expectoration the drug had little influence. All the patients obtained a better and quieter sleep. In two there was on the following morning headache and general malaise, while two complained of nausea and constipation. These are symptoms which often follow the administration of morphin, of which peronin is a derivative. Schroeder looks upon this remedy as holding a middle ground between morphin and codein, and considers it worthy of a further trial. It is capable of giving relief, but not, of course, of curing the cough, and is therefore to be classed with other narcotics as one of the reserve methods of treatment.

Influence of Cold Baths in Delirium Tremens.—LETTULE (*Centralbl. für Ges. Ther.*, January, 1897) recommends as a sedative in delirium tremens a cold bath of 65° F., the patient being immersed in the water to his shoulders, while water of the same temperature is poured over his head. In a severe case in which large doses of morphin subcutaneously and chloral by the mouth had failed to give sleep in two days and death was expected, a bath of the temperature of 65° F., increased in the first three minutes cyonosis and excitement. In six minutes the aspect of the patient completely changed. His excitement disappeared, he seemed to awake from a dream, asked where he was, drank eagerly two glasses of warm wine, and wanted to sleep. He was placed in bed and immediately fell asleep. The following day, on account of recurring excitement, it was necessary to repeat the bath four times. There was no further delirium and the patient recovered. In a second case it was necessary to leave the patient twelve minutes in the bath, when as suddenly as before there was quiet, thirst, and a desire for sleep, followed by complete recovery in two or three weeks.

For Obstinate, Acute Intestinal Catarrh.—

℞	Resorcin		grs. lxxv
	Bismuth salicylate Tannigen	aa	℥ ss.
	White sugar Sodium carbonate	aa	ʒ ii

M. Ft. pulv. Sig. small, even teaspoonful every two hours.

—Ewald.

For the Severe Constipation of Dyspeptics.—

℞	Podophyllin		grs. v
	Ext. of nux vomica Ext. of calabar bean	aa	grs. vii ss.
	Ext. of gentian Licorice powder	aa	q. s.

M. Ft. pil. No. XXX. One pill twice daily.

—Einhorn.

Pruritus Treated by Salophen.—WANNEMACKER (*Wien. Med. Blät.*, March 4, 1897) has obtained good results in the treatment of pruritus from the use of salophen in doses of dram daily. In some cases a cure was effected in one day; in others, it was necessary to continue treatment for a week. Some of the patients had suffered for years, and had tried various remedies without benefit. Cases of eczema complicated by obstinate itching were also improved by this treatment.

Guaiacol in Puerperal Eclampsia.—In the *Boston Med. and Surg. Jour.*, March 18, 1897, APPLEBY speaks of the use of guaiacol in two cases of puerperal eclampsia with happy results. Each patient was a primipara. In one, the convulsions had come on during the third stage; in the other, after delivery. In both the convulsions were powerful and almost continuous. Forty or fifty drops of guaiacol were poured upon the abdomen and gently rubbed in. In a few minutes the pulse became soft, free diaphoresis set in and the convulsions ceased. Both patients recovered perfect health without further convulsions. If these had recurred the writer would not have hesitated to use guaiacol the second time.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

KOCH'S IMPROVED TUBERCULIN.

ATTENTION has been attracted with renewed interest to Prof. Koch and his work in connection with tuberculosis by an article of his which appears in the last issue of the *Deutsche Medicinische Wochenschrift.* In this article Prof. Koch points out the fact that the comparative lack of success in procuring an efficient antitoxin from the tubercle bacillus is due to the circumstance that this particular germ is exceedingly tenacious of his products, and does not readily give them up to the tissues. This micro-organism, when injected subcutaneously in gradually increasing doses, as is done with the diphtheria bacillus, does not develop antitoxin in the blood in sufficient quantity to be used for therapeutic purposes as does the latter, but harbors his own resources within himself, and goes forward with his destructive work. In exceptional cases, however, sufficient antitoxin is developed to counteract the toxins, and these cases recover.

It becomes necessary, therefore, to devise some artificial means of compelling the bacillus to give up those products which are essential to the development of the antitoxins. At first the active elements were extracted from the bacillus in glycerin and evaporated by heat. This was the original method of procuring tuberculin. This proved only partially efficacious, as is well known, and was open to the objection that injections of it were apt to cause abscesses. It, however, had sufficient virtue to be recognized as a reliable diagnostic test, not only in cattle, but more recently in man at so early a stage of tuberculosis that clinical observation and physical examination were not yet of any avail.

Inspired by this success, and sustained by his faith in the great principle of antitoxin therapy, Prof. Koch continued to study the elements of failure, as well as of success. He reached the conviction that in his process of extraction, the characteristic properties were partially destroyed by the chemical processes and by the heat, and that the solution of the dead bacilli was the cause of the abscesses. By a careful system of staining he found that the bacillus is possessed of an integument which, doubtless, protects it from external attacks, and renders absorption and assimilation of it difficult. It became necessary, therefore, to destroy this integument. After many futile attempts to accomplish this by methods which would not destroy the characteristic properties, Koch conceived the idea of grinding the dried bacilli in a mortar. When well-dried cultures were taken and worked about for a long time in an agate mortar, without any admixture, it was seen that the bacilli gradually lost their contour, and became reduced to a powder, and that, finally, only a few remained. In order to remove these, Koch diluted the substance thus obtained with distilled water, and clarified it by means of a very powerful centrifugal machine which made 4000 revolutions in a minute. The fluid was in about half an hour divided into a whitish, opalescent, but quite transparent, upper layer, which contained no more bacilli, and a muddy sediment sticking fast to the bottom. The latter was again dried, then triturated in the mortar, dissolved and clarified by the machine, and separated as before. This manipulation was continued till finally nothing remained but a series of completely clear fluids.

To secure all the toxic properties in their most active form only the fresh, living, most virulent cultures are used, the bacilli being taken from the surface of the culture-broth and dried by the vacuum process. At first Koch convinced himself by experiments on animals and, later on, on human beings, that the preparations so gained were all completely "resorbable," and never caused abscesses. It was further shown that though the first fluid differed considerably from the others, they all produced similar effects.

With this preparation experiments have been made on animals and man, both for immunizing purposes and for cure in the early stages of tuberculosis. Results have been most satisfactory. It is evident that the improved tuberculin is much better than the former preparation, although Koch modestly asserts that he does not believe it to be ultimate perfection; in other words, it is capable of still greater improvement.

ANTISTREPTOCOCCIC SERUM.

In this age of serotherapy it is not surprising to find a remedy of this character offered against streptococcic infection, which hitherto has carried such a heavy mortality rate. Foreign and home journals teem with reports of cases where the antistreptococcus serum has been used, and the difference of opinion as regards results obtained is most marked. Fully as many observers report failure as success, and it becomes a matter of difficulty to decide—even granted that the time is ripe for the expression of decided opinion—whether this serum, so vaunted by some, is, after all, of any utility whatsoever.

At the outset, observers appear to have forgotten two very important points: In the first place, the serum, if efficacious at all, is only so in the presence of the streptococcus; and in the second place, even though the infection be due to the streptococcus, if it be localized, or if operation be performed before lymphatic, systemic absorption occur, the case will very frequently recover without utilization of the serum. Further still, current literature contains reports of cases of what is termed puerperal sapremia which have recovered through the use of the serum plus resort to the usual surgical measures, and yet the open fallacy is that similar cases constantly recover through curettage and drainage without the serum. On the other hand, we find instances recorded in which, notwithstanding surgical measures of the most radical type, the cases were progressing from bad to worse, when the use of the serum altered the prognosis absolutely. Little wonder, then, that enthusiasm causes certain observers to contend that they have found a specific against streptococcus infection, and insist that in every case in which we have reason to expect such infection the serum should be administered as an *immunizing* agent.

From a careful study of a large number of reported cases, it would seem to us that so far the verdict of "not proven" must be rendered. Frequently the temperature has fallen, the heart action has improved, and the eliminative power of the kidneys has been bettered through the use of the serum; but in probably as many instances no appreciable change in the subjective phenomena has been obtained, and in one instance at least the serum apparently caused grave lesion of the kidneys. And yet, to be absolutely fair, in the latter instance no one is in a position to say that the disease itself—septic infection—was not responsible for the renal involvement.

If, as is contended, the injection of the antistreptococcic serum is followed by increased leucocytosis and consequent phagocytosis, we are possibly on the verge of the discovery of an agent of untold therapeutic value, since it will follow that, given a serum effective against one germ, there is reason to expect the discovery of serums effective against other septic germs. Our apparent lack of success up to the present time may be due to imperfect or insufficient administration of the serum. Probably the safe plan for practitioners to follow is that of never neglecting those early and radical surgical measures which at times save even an apparently hopeless case, and at one and the same time to utilize a serum obtained from a reliable source and free from extraneous substances, such as carbolic acid, on the ground that it is hardly likely to do harm and may do a world of good. Certainly the accredited standing secured by other serums, notably the antidiphtheritic, should lead us to avoid pessimism in regard to the value of other varieties of serum, even though we apply the scientific curb to our enthusiasm.

ECHOES AND NEWS.

State Aid for a Medical School.—A bill before the Texas Senate appropriates $42,000 annually for the medical department of the State University.

A Civil Service Appointment.—Arthur J. Caperon, M.D., of Rochester, has been appointed from the civil service list junior physician at the Manhattan State Hospital, Randall's Island.

Dr. William H. Thomson Resigns.—It is announced that Dr. Thomson has resigned from the Chair of Practice of Medicine in the New York University.

The Medical College of Ohio.—This institution held its Seventy-eighth Annual Commencement exercises on April 9th, and graduated one hundred and eleven students.

Doctors as Lawmakers.—The recent general election in Italy resulted in the return of forty members of the medical profession to the Italian Parliament, many of them occupying leading positions.

Two French Doctors Punished.—Drs. Boisleux and De la Jarrige, of Paris, who were convicted recently for having murdered an English girl by an operation for procuring abortion, have each been sentenced to five-years' imprisonment.

Cerebrospinal-Meningitis in Boston.--Fifty cases of this disease have been reported to the Board of Health at Boston during the past thirty days. The cases are said to be found in all parts of the city, and among all classes of people.

Why Fashions in Surgery Change.—The quotation from Mr. Lawson Tait in our last issue should read: "The absence of *inquiry into* secondary results is the cause of so much change of fashion in surgery, to say nothing of medicine."

American Academy of Medicine.—The Twenty-second Annual Meeting of this Society will be held in Parlor "C" of the Continental Hotel, Philadelphia, on Saturday and Monday, May 29 and 31, 1897. The advance program announces discussions on about all the ethical questions ever dreamed of in medicine.

Vegetarians in England.—Advanced vegetarians in England have formed an association, binding themselves to eschew not only animal food, but also all articles composed in any degree of substances involving the death of animals. This includes leather for shoes and gloves, fat for soap, ivory, skins, and feathers.

An Englishman's View.—An Englishman, who signs himself in the *Lancet* "A British Exile," and who has evidently been investigating the hardships endured in the pursuit of a medical education and practice in America, says: "To the English medical man who has ideas of starting for this field there is only one good piece of advice—'Don't.'"

Dr. Biggs of New York Honored.—Dr. Herman M. Biggs has been selected to deliver the Address on Public Medicine before the British Medical Association at its meeting in Montreal. We can justly regard it as a most flattering tribute to American medicine that two of the three men selected to deliver general addresses before the Association have been chosen from the United States.

A Woman Graduate at Vienna University.—Vienna University has accepted the inevitable and granted the degree of Doctor of Medicine for the first time to a woman, the Baroness Possauer von Ehrenthal, who recently was admitted to practice in Austria after passing the requisite State examination. She had received the degree from Zurich many years before.

Hard Times as a Preventive of Sickness.—The *Canadian Journal of Medicine* has discovered that a reasonable explanation of the hard times theory of exemption from sickness is that a long, strong dose of misfortune is either a powerful tonic to the brain and nervous system, or a depressing influence which leads to despair and suicide.

Medical Inspectors for Industrial Schools.—It is proposed to extend the system of medical inspection recently introduced into the public schools of New York so as to include the industrial schools in charge of the Board of Education, as well as those under the supervision of the Children's Aid Society. There are twenty-three industrial schools in the city, with 6354 pupils.

House of Refuge in New York Quarantined.—The House of Refuge on Randall's Island was recently found to contain a large number of cases of trachoma, as well as a general epidemic of measles, and has been quarantined by the Board of Health, careful isolation being established among the inmates. The Finance Committee of the State Senate has voted to allow an appropriation of $32,700 for the sanitary improvement of the buildings.

New Building for the Hospital for Ruptured and Crippled.—Plans were filed recently with the New York Building Department for the addition to the Hospital for the Relief of Ruptured and Crippled. The new structure will occupy the entire northern part of the block between forty-second and forty-third streets and Lexington avenue. The new building will cost about $250,000. Work has already begun.

A New Hospital in Washington.—A hospital for the treatment of the eye, ear, and throat has just been established at the corner of Seventeenth and L streets. The attending physicians are Drs. William H. Fox, William H. Wilmer, Franck Hyatt, E. Oliver Belt, T. Morris Murray, and J. H. Bryan. The consulting board is composed of Drs. Samuel C. Busey, J. Taber Johnson, J. F. Thompson, W. W. Johnston, N. S. Lincoln, and J. W. Bayne. A graduate of Bellevue Hospital training school has been secured as superintendent.

The Nurses' Settlement.—It is often said that only the very rich and the very poor can command the services of a trained nurse. The Nurses' Settlement of New York, established about five years ago in Henry street, has proved beyond question that the services of a trained nurse are also within the reach of wage-earners. The plan is to send a nurse to a patient for one, two, or three hours, as the circumstances may require. In this way she can see several patients in a day. The fee charged is thirty cents an hour.

The Health of New York City.—A report of the Board of Health shows that the death-rate of the city for the first three months of this year is lower than it ever has been for corresponding periods in many years. The following table shows the comparative number of deaths and the comparative death-rate for the first quarter of each year since 1891:

Year.	No. of Deaths.	Rate.
1891	10,214	24.99
1892	11,458	27.23
1893	11,844	27.33
1894	10,976	24.63
1895	11,728	25.34
1896	10,949	22.96
1897	9,957	20.31

Smallpox in New York.—The eighteen cases of smallpox which have made their appearance in this city since March 1st, have increased the work of the medical inspectors in the Bureau of Contagious Diseases of the Health Department to such a degree that it has been found necessary to increase the staff temporarily, so that the work of examination may be expedited. In each of the eighteen cases a medical inspector has been assigned from the regular staff to keep a strict daily watch on the house from which the patient was removed, and in consequence of this the regular corps of vaccinators has been diminished to that extent. In every case of smallpox reported inspectors are at once sent to vaccinate the persons living on the four sides of that block, and also on the four sides of the adjoining block. The disinfecting corps has been kept busy as well.

Doctors Held for Blackmail.—It is reported that Dr. J. W. Prendergast, Health Officer of Cincinnati, and Dr. Ovlimerick, after a hearing before Magistrate Winkler lasting nearly a week, have been bound over in $1000 each to the Grand Jury on the charge of blackmail preferred by H. N. Fraser of the Fraser Tablet Co. of New York. The Tablet Company charges that the Health Officer at first demanded $10,000, claiming that the tablets were impure or short in strength, and that the Pure Food Commission would consequently prohibit their use by the Health Department. This fact, on being noised abroad, would work the company injury. The sum demanded, according to the Tablet Company, was finally reduced to $2000. The company denied that the tablets were not as represented, and caused the two doctors' arrest.

Tuberculosis in Massachusetts.—As the result of a recent investigation made in Massachusetts by the legislative Committee on Public Health, a statement has been prepared, explaining how consumption is propagated and how best it may be combated. The document contains nothing new, and is notable only because of the emphasis with which it advocates the segregation in special colonies of all sufferers from the disease whose circumstances are such that they cannot receive at home the sort of care that will prevent them from being dangerous to the community in which they live. It is recommended that these patients be placed in suitable hospitals or homes, in localities where the air is dry, where outdoor life is possible during the greater part of the year, and where they would not imperil the safety of other people. This suggestion is signed by two professors in the Harvard Medical College, by the Chairman of the Boston Board of Health and Park Board, by the medical examiners of Suffolk County, and by the chairman or medical member of sixteen other towns and cities in the State.

Mr. Roosevelt's Opinion of the New York Board of Health.—The *Evening Post* quotes the retiring Police Commissioner as follows: "As President of the Board of Police, I have been a member of the Board of Health, and it has been a real pleasure to work with three such men as Mr. Wilson, Dr. Fowler, and Dr. Doty, and to have some small part with them in rendering the invaluable service to the city which they have rendered. During the entire two years I have never known them to take one step that was not dictated solely by an earnest desire to benefit the public, and to do in the best possible manner work which it was necessary to have done. The work which they have done toward eradicating those noisome pest-houses, the rear tenements, is of such far-reaching importance that people can form but a faint idea of it. The work of the board in regard to tuberculosis, steadfastly pursued in spite of all clamor, the effort to get pure milk for the people, to secure proper sanitary conditions in tenement houses, and the crown of it all, I am tempted to say, the medical inspection of schools, just begun by the board—all these are illustrations of the various kinds of work which go to make up the splendid record of efficiency of the department. It has been a pleasure to work with a department presided over by so admirable an executive head as Mr. Wilson, and to be able to second and speed the efforts of his colleague, Dr. Fowler, and himself."

Obituary.—Dr. Francis Wilhoft, sixty-two years old, a well-known physician and inventor, died at his home in New York, April 12th, after a brief illness. He was born in Germany, and was graduated with high honors. He came to this country in 1857, and settled in New Orleans where he built up a large practice. In 1880 he came to New York City, and two years later became interested in a new process for working and vulcanizing rubber, and retired from practice, devoting his whole time to this work. He was a frequent contributor to foreign medical journals. He leaves a wife and five children. The body was cremated at Fresh Pond, L. I.—Dr. Andrew Otterson, an old-time Brooklyn physician, died suddenly April 15th, at his home, in Brooklyn, of heart disease. He had been ill for several days, and appeared to be in a fair way of recovering, when he was stricken. Dr. Otterson was born seventy-five years ago in Montgomery County, N. Y. He was graduated from the University of the City of New York in 1844, and removed to Brooklyn, where he practised without intermission until his death. In 1874 he was appointed Health Commissioner, and was reappointed in 1878, and again in 1882.—Dr. Charles M. Shields died in Richmond, Va., April 16th. His death was from tuberculosis, contracted from a patient whom he treated. This fact attracts very general interest among the medical profession. Dr. Shields enjoyed one of the most lucrative practices in Richmond, although only thirty years old.

CORRESPONDENCE.

THE MEDICAL APPRENTICE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Your excellent editorial on "Ethics in Medical Schools," which appeared in the issue of the MEDICAL NEWS of March 13th, is timely, and to the point. If a "reversion to the old apprenticeship system is impracticable," as you say, something equally as good might be suggested.

The personal equation is so important to a successful practice, that it ought to be taught in some way. The terms "apprentice" and "apprenticeship" smack too much of *trade* to be agreeable to a professional man, but the old term, "articled pupil," might be used to express the status of the medical aspirant.

Before matriculating at a medical college, every medical student should be required to serve one year in a physician's office, in order to secure just the advantages described in your editorial. For this privilege, $50 to $500 might fairly be demanded by the preceptor for his services for training, use of office, wear and tear of books, etc.

An American youth of seventeen or eighteen years of age should be able to acquire, by that time, a fair English education (including a reading knowledge of French and German) or the equivalent of an A.B. course, and this, with a four-years' course in medicine (including one year of hospital work), should fit a young man for medical practice at as early an age as it would be prudent to allow him to assume such responsibility.

We sadly need an entire change in our system of education.

Yours truly,
"C."

NORFOLK, VA., March 21, 1897.

CRITICISMS OF THE NEW CHARTER.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Among the criticisms of the new charter, none has been more severe than that directed against Sections 1247–1249, relating to the duties of physicians in reporting cases of contagious and infectious disease. These sections are referred to as if they were entirely new and unprecedented and designed to give the Health Department a dangerous and tyrannical authority over the members of the medical profession. Now, the fact is that these sections are not new. They constitute Sections 608–610 of the Consolidation Act of 1882, under which the city has been governed for fifteen years, and were originally passed forty-seven years ago, Sections 1247 and 1249 being in Chapter 275, Laws of 1850, and Section 1248 in Chapter 384, Laws of 1851.

Very truly yours,
GEO. B. FOWLER, M.D.,
Commissioner.

HEALTH DEPARTMENT,
NEW YORK, April 14, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

AMERICAN MEDICAL ASSOCIATION MEETING—THE RAZING OF AN OLD HOSPITAL BUILDING—SUMMER INSTRUCTION IN MEDICINE—DR. JOHN W. CROSKEY—SECTIONS ON GENERAL MEDICINE AND GYNECOLOGY OF THE COLLEGE OF PHYSICIANS—PHILADELPHIA COUNTY MEDICAL SOCIETY—A NEW "SPITTING ORDINANCE"—EXAMINATIONS FOR ASSISTANT CITY BACTERIOLOGIST.

PHILADELPHIA, April 17, 1897.

FROM present indications the local committee of arrangements looks for not less than two thousand members at the meeting of the American Medical Association in this city next June. Considering that this will be the jubilee of the association in its birth-place, and that Philadelphia offers many attractions to the visiting medical man, it may be that this large estimate is within bounds; and yet, when it is recalled that at last year's meeting at Atlanta only 750 members were present, and also that here, in the East, a large number of the profession are lukewarm, to say the least, in their interest toward the association, it is unsafe to predict so large an attendance. However, be the number large or small, elaborate preparations for their entertainment are being made, both at the leading hospitals and medical schools, while excursions to various points of interest are already planned. The association will be tendered a large reception at the Academy of Fine Arts by the Jefferson Medical College, and are to be entertained by the University of Pennsylvania at the Union League Club. The meeting will terminate in a series of banquets on June 4th, when each of the thirteen sections will give a dinner to its particular guests.

Laboratory demonstrations on practical points of interest have been arranged for the visiting members during the week preceding and the week following the meeting, by the joint action of the faculties of the Jefferson, Medico-Chirurgical, and University Medical Schools. The following demonstrations will be given at the above institutions at ten o'clock A.M., May 27, 28, 29, and June 7, 8, 10, and 11; "Practical Bacteriology," by Dr. A. C. Abbott; "Skiagraphy," by Dr. C. L. Furbush; "Clinical Microscopy and Autopsies," by Dr. A. A. Stevens; "Clinical Microscopy," by Dr. H. F. Harris; "Pathology," by Dr. D. Riesman; "Skiagraphy, Practical Disinfection, and Autopsies," by Dr. W. M. L. Coplin; "Widal's Serum Test," by Dr, J. C. Da Costa, Jr.; "Rare Tumors," by Dr. J. McFarland; "Skiagraphy," by Dr. M. J. Stern; "Surgical Disinfection," by Drs. J. Chalmers Da Costa and T. L. Rhoads; "Urinalysis," by Dr. J. Marshall; "Bacteriology," by Dr. B. Lewis.

The destruction of the Men's Receiving Ward of the Pennsylvania Hospital, to make room for a more modern structure, removes an old landmark from the medical world of this city, and wipes out the many historical associations of the Revolutionary war and Colonial days which were so intimately connected with the old building. It was erected in 1756 as a laboratory, and was occupied first by the Colonial Army as a medical supply depot, and later by the British troops during their occupation of Philadelphia during the winter of 1777.

That Philadelphia medical colleges of the better class recognize the need for instruction, other than that offered during their regular sessions, is shown by the very satisfactory courses announced for the coming summer by the Jefferson Medical College and the University Medical School. The laboratories of the former institution, by far the best equipped in the city, will remain open from May to October, for both post-graduate and undergraduate instruction in morbid anatomy and histology, normal histology, and bacteriology. At the Pepper Laboratory of the University of Pennsylvania post-graduate courses are announced in physical diagnosis, skiagraphy, and the various branches of pathology and clinical microscopy.

Dr. John W. Croskey has been elected one of the attending surgeons to the Wills Eye Hospital, to fill the vacancy caused by the death of Dr. P. D. Keyser. The election of Dr. Croskey was made from a large field of candidates for the place, which is considered by ophthalmologists of one of the most desirable offices in their specialty.

At the last meeting of the Section on General Medicine of the College of Physicians, held on April 12th, Dr. William Osler of Johns Hopkins University, presented a masterly paper on "The Ball-valve Stone in the Common Duct." Dr. Osler recounted his already well-known views concerning this condition, and exhibited specimens illustrating his subject. A paper was read by Dr. Alfred Stengel on the "Diagnosis of Atheroma of the Arch of the Aorta." Dr. Wm. G. Spiller read, by invitation of the Section, "A Contribution to the Study of Spinal Syphilis." Other papers were read by Dr. Frederick A. Packard, and by Dr. A. E. Taylor.

At a stated meeting of the Section on Gynecology of the College of Physicians, held on April 15th, Dr. John C. Da Costa read a paper on "Pyemia in Infancy"; and Dr. Barton C. Hirst, on "Two Cæsarean Sections—One for Dermoid Cyst Impacted in the Pelvis, the Other for Flat Rachitic Pelvis and Overgrown Child."

The last stated meeting of the Philadelphia County Medical Society was held on April 14th. Dr. A. Ferree Witmer in the course of his very instructive study of the subject, "Is There a Daily Rhythm in Epilepsy?", showed that in the large number of cases of this disease which he had investigated the greatest number of epileptic attacks occurred at 4 A.M., and 4 P.M., that is, at the periods of greatest general vital depression. Dr. Witmer showed a number of composite charts, comprising the records of many cases, and from which he made the deductions embodied in his paper. Regarding the treatment of epilepsy, he said that in his experience the best results were obtained from the use of glycerin, in two-dram doses, after meals; and that this drug when used alone gave better results than when it was combined with bromid. Dr. Joseph Price, in a paper on "Some of the Common Causes of Mortality in Abdominal Surgery," dwelt with emphasis on the importance of the necessary qualities of the surgeon himself as relating to thorough competency, ability to combat emergencies, familiarity with technics, and large experience; and said that a thoroughly educated nurse was also one of the essentials of a successful practice of this specialty. Dr. Mordecai Price read a paper on "Extra-uterine Pregnancy."

Philadelphia is far behind in the question of improvement in many hygienic matters, but she proposes to keep pace with New York and Chicago, in at least one respect, by placing a five-dollar penalty on public expectorators. The present legislation is the outcome of some years' agitation by various local health associations, and it is hoped that the more stringent measures embodied in the new law will accomplish more than the recent, ineffectual prohibitory notices of the Board of Health—prohibitory, but without the restraining influences of the five-dollar penalty.

A civil service examination was held on April 17th, for the position of Assistant Bacteriologist to the Board of Health. It is understood that the successful candidate's name will be announced some time during the coming week.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

CLINICAL BEARING OF SOME EXPERIMENTS ON PERITONEAL INFECTION—PULSATING EMPYEMA—SOME CASES OF INTESTINAL NEUROSIS—GUMMATA OF THE KIDNEY—A PECULIARLY CANCEROUS FAMILY HISTORY—HYDROCYANIC ACID AS AN ANTIDOTE FOR CHLOROFORM.

AT a meeting of the Royal Medical and Chirurgical Society, held March 8th, DURHAM read a paper on *the clinical bearing of some experiments on peritoneal infection.* It has been found that injections of sterile water, broth, or serum into the peritoneal cavity of an animal will confer upon that animal a certain amount of protection against subsequent infection. This is due to (1) increased bactericidal power of the peritoneal fluid, and, (2), the presence of a very large number of active phagocytes, which are not seen in normal peritoneal fluid. In certain fatal cases of peritonitis in which death rapidly follows the onset of symptoms, no lymph or organisms may be found at autopsy in the peritoneal cavity; but if the lymph spaces in the omentum and back of the peritoneum be examined, abundant organisms may be found. The suggestion was made that the injection of a sterile fluid into the peritoneal cavity of a human being, the day preceding an operation for appendicitis, or for pyosalpinx, etc., would afford a certain amount of protection against purulent infection; and, as fatal peritonitis is often due to streptococci, Durham recommended the use of antistreptococcic serum in this manner.

At the meeting of March 23d, WEST read a paper on *pulsating empyema*, which he described as a rare phenomenon. The pulsation is of two kinds: (1) A general shock usually communicated to a considerable area of the chest wall—intrapleural pulsation. (2) Expansile pulsation localized in an external tumor—extrapleural pulsation. Either variety is usually met with on the left side, and is synchronous with the heart's systole.

Intrapleural pulsation is usually felt, but not seen. Its diagnosis is not difficult. Extrapleural pulsation is met with in empyema only when "pointing." There may be two or more tumors, and situated even as remote as the loin; but oftener there is a single one near the heart. Such a swelling has been mistaken for an aneurism. Puncture with a fine needle is unaccompanied by danger in either case, and will settle the diagnosis at once.

The cause of pulsation has been much discussed. Obviously the heart's impulse must be felt in every large effusion in the left side of the chest, but this is not evident externally unless all the walls of the cavity in which the fluid is contained are rigid; and, as a matter of fact, in these cases both lung and mediastinum are found, *post-mortem*, to be both thickened and rigid. The prognosis is bad, not because of the pulsation, but because the conditions under which it occurs, namely, the fixation of the heart, and the changes in the mediastinum and lungs are such as to prevent their cure.

DENT read a paper before the Medical Society on March 8th upon *intestinal neurosis*, in which he described three cases presenting symptoms of grave abdominal trouble. In one there was severe epigastric pain after eating, supposed to be due to a stricture in the small intestine. There was emaciation and a distinct tumor above the umbilicus which persisted during narcosis. An exploratory incision was made, but nothing was found. All the symptoms disappeared. In another case, in which the swelling was felt in the right iliac fossa, nothing was found on operation, except a slight adhesion between the cecum and the omentum, but while the belly was open the first few inches of the colon were seen to contract into a rounded mass, which, no doubt, explained the occurrence of the tumor felt before operation. There was only temporary relief of the symptoms. In a third case, in which pain was so severe as to cause vomiting, but in which nothing abnormal could be felt, the symptoms were entirely relieved by abdominal massage.

At the Pathological Society meeting, held March 16th, BOWLBY showed a large renal tumor which he had removed from a stout, healthy woman, aged forty, who had suffered twenty-one years previously from syphilis, though for nineteen years there had been no manifestations of the disease. Other than an occasional trace of albumin in the urine, and the presence of an increasing tender swelling in the right loin, the tumor gave no symptoms. When removed the kidney weighed over a pound, and was so full of gummata that it was difficult to find any trace of the renal tubules. As there was no diminution in the amount of urine after the operation, and two years later the health of the patient was excellent, there was every reason to believe that the other kidney was sound.

RICHMOND described to the Pathological Society of Manchester, March 10th, a case of *periosteo-sarcoma of the radius occurring in a girl, aged nineteen, whose family history was peculiarly malignant*. The father's aunt died from a tumor of the breast, and the father's brother died at the age of thirty-four from a tumor of the thigh, which developed after an injury. Of the mother's sisters, one died at the age of sixty from cancer of the face, which developed after an injury; and another died from a tumor of the womb. In the present case there was a history of less than five-months' duration, in which, the left wrist, from a slight enlargement, had reached a circumference of nineteen inches. Microscopically, the tumor consisted of large spindle and large round cells.

At a meeting of the Society of the Anesthetists, held February 18th, HOBDAY urged the use of *hydrocyanic acid as an antidote for chloroform*. In animals when symptoms of danger occur he places a full medicinal dose of the chemically pure acid on the back of the tongue by means of a drop-tube and commences artificial respiration. Theoretically, this drug is a perfect antidote in chloroform poisoning, being one of the most rapid and strongest respiratory stimulants, as well as a cardiac stimulant, and it is rapidly absorbed from mucous membranes without irritation. Practically, he has found the use of hydrocyanic acid to be in accord with the theory.

Berlin.

A PECULIAR DISEASE OF THE BONES OCCURRING IN WORKERS ON MOTHER-OF-PEARL — INTESTINAL STENOSIS AND PERFORATION DUE TO AN INVERTED MECKEL'S DIVERTICULUM — DILATION OF THE ESOPHAGUS FROM AN UNUSUAL CAUSE—LACK OF DEVELOPMENT OF THE LOWER JAW .ASSOCIATED WITH ANKYLOSIS.

LEVY addressed the Medical Society, February 3d, upon *a peculiar disease of the bones occurring in workers on mother-of-pearl*. A patient was presented the lower end of whose left humerus was extremely painful and considerably enlarged. The disease affects the diaphysis, near the epiphysial line; and in the six cases which Levy has observed, the inflammatory swelling subsided without the formation of a sequestrum. Gussenbauer considered the cause of the disease the inhalation of the dust produced in cutting the shells. This dust would contain about ninety-five per cent. of calcium carbonate and five per cent. of an organic substance called conchyolin. He supposed that the lime was absorbed in the lung, and the conchyolin being introduced into the circulation, settled in the diaphyses of the long bone. Experimentally it has not been found possible to reproduce the disease in animals. Levy held to the view that the slime which is found on all sea-shells was the cause of the disease, but in his experiments numerous attempts to reproduce the disease in young rabbits, by subcutaneous injections of the slime, all failed.

EWALD showed a specimen, at a meeting of the Union for Internal Medicine, held February 15th, obtained from a woman, aged forty-two, who, in the last eighteen months, passed through several attacks of obstipation and bilious vomiting, lasting several days. The attacks grew more and more frequent, and recently the peristaltic action of the intestine, during an attack, could be plainly seen and felt. The patient died suddenly, and as many of the attacks were associated with jaundice, her death was attributed to a perforation brought about by a gall-stone. At the autopsy a peculiar condition of affairs was discovered. A Meckel's diverticulum was inverted, like the finger of a glove, into the lumen of the bowel, dragging the mesentery in with it. At this point there was an inflammatory stenosis, so that the caliber of the bowel was scarcely the size of a lead-pencil. In the center of the inflammatory area was a perforation, which was the starting point of general suppurative peritonitis.

JAFFE described a case of dilation of the esophagus, in the Medical Union of Hamburg, February 2d, occurring in a man, aged fifty-two, with well-marked kyphoskoliosis, in which the diagnosis lay between nervous dyspepsia and carcinoma of the cardiac end of the stomach. At the autopsy it was found that the xiphoid process was bent backward, and so closely approximated to an especially prominent dorsal vertebra as to flatten the cardiac portion of the stomach. The lower part of the esophagus was dilated so as to measure eleven centimeters in circumference. It was suggested that an esophageal tube would have relieved the symptoms if left in position for several days; or through a gastric fistula dilation of the constriction might have been performed. The insertion of permanent hollow tubes (Leyden-Renvers), even at the depth of the cardiac orifice, presents no great difficulty, and these tubes can be used for months without an injurious effect. A radiograph of this case was shown, the esophagus being filled with a five-per-cent. solution of subnitrate of bismuth, while a rubber tube filled with shot was passed into the stomach.

At the session of the Medical Society held March 3d, WOLFF presented a patient, a male, aged seventeen, with *congenital smallness* ("*micrognathia*") *of the lower jaw associated with ankylosis.* Such cases are extremely rare, some of them being strictly congenital, and others due to suppurative processes in infancy, followed by ankylosis and lack of development of the lower jaw. In the case presented it was only possible to insert the tip of the little finger between the teeth, and eating was a long and difficult process. The surgical treatment of these cases has been far from satisfactory. Perhaps the best result was obtained by Von Bergmann who resected both coronoid and condyloid processes. In this case, by means of an ingenious plate, the lower jaw was extended forward more than a third of an inch.

KOENIG said that in most of these cases the condition was an acquired one, being a result of osteomelitis in the lower jaw, an infection which is by no means uncommon in the first year of a child's life. The result is that the development of the jaw is imperfect on the infected side, and in the case presented a difference in the two sides was plainly noticeable. If enough of the condyloid process, and possibly of the coronoid also, is removed so as to permit the teeth to be separated for a reasonable distance, the ankylosis will not recur. Von Bergmann thought such cases not as rare as Wolff supposed. He himself had performed operations for their relief six or seven times.

An American Physician Honored.— It is with no little satisfaction that the NEWS chronicles the election of Dr. Abram Jacobi of New York as Corresponding Member of the Royal Medical Society of Vienna.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting held January 20, 1897.

The President, DR. CHARLES L. DANA, in the Chair.

SYPHILITIC NEURITIS.

DR. JOSEPH COLLINS presented a man, twenty-four years old, by occupation a box-maker, who had been well until ten months ago. He denied syphilitic infection, and used liquor and tobacco in moderation. History of the present illness dated back ten months, when an attack of dysentery began. For six months he had had bloody stools, with consequent emaciation and weakness. After this ceased, he became very nervous, and complained of pain and "sticking" sensations throughout the upper extremities, which he described as rheumatic pains. They were not severe enough to confine him to his home. One day, about six weeks ago, on coming down the steps of his house, he began to feel dizzy and weak, and then fell. He did not lose consciousness, except, possibly, for a moment. The strength of the lower extremities completely forsook him, and there was a tetanic spasm (contracture of both upper extremities), lasting several minutes. He was unable to get back into the house, for, although his legs were not completely paralyzed, he could not stand. The paresis of the legs disappeared entirely after a few days. The weakness of the arms and forearms was so great that he was not able to perform any voluntary act.

When he came under observation, examination showed atrophy of both shoulders and of the upper arm, symmetrically distributed. There was inability to draw the shoulders backward, even to the slightest degree. He could raise both arms simultaneously to a right angle with the body, and could raise them individually somewhat higher than this by tilting the body backward. The muscles that were particularly atrophied were the supra- and infraspinatus, the deltoid, and the trapezius. Electrical examination showed a complete reaction of degeneration; *i. e.*, absence of reaction to the faradic current in all the muscles of the upper arms and shoulders, excepting the trapezius and biceps, and in the latter there was partial reaction of degeneration manifested by vermiform contraction. There was scarcely any reaction to the galvanic current. There was no sensory defect to be made out, nor was there tenderness on pressure of the mixed nerves, such as the brachial plexus and its branches. The left knee-jerk was quick and abrupt, the right rather slow. The sphincters were unimpaired, and the patient is fully potent.

Treatment consisted of the administration of tonics, small doses of iodid of potassium, and the utilization of electricity and hydrotherapeutic measures. The patient has improved considerably. When first seen, he was unable to feed himself; he could now do this and was able to dress without assistance, and, in a general way, look after himself. The improvement could be noticed from week to week.

The speaker said that the probable anatomic diagnosis was a vascular lesion which cut off the blood supply going to the vertebral horns or cornuæ of the spinal cord in the midcervical region, although it was barely possible that the lesion was of the gray matter itself—an acute parenchymatous inflammation of the anterior horns; still, certain features in the case, particularly of its onset and development, were inimical to such a conception of the pathogenesis of the lesion. It seemed to him that the interpretation to be put upon the case was as follows: The patient had suffered from a specific disease for several months, and the consequences were that it not only depleted the entire system, but injurious influences were exerted particularly, and for inexplicable reasons, upon the blood-vessels distributed to the spinal cord. Without attributable exciting cause, one of these blood-vessels either ruptured or became occluded in its caliber, and it is probable that this vessel was one of the branches of the anterior spinal artery as it passes down into the anterior median fissure. The acute phenomena accompanying such a lesion were manifested by tonic tetanic spasm of the upper extremities, dizziness, momentary and transitory loss of consciousness, great prostration, and more or less quadriplegia. The weakness of the lower extremity, however, disappeared almost at once, the only paralysis remaining being that dependent upon cessation of function of those cells in the cervical spinal cord which preside over the movements of the upper extremities. After the obstruction, or the results of the hemorrhage had been removed, and the acute exudative phenomena had subsided, the return of volition to some of the muscles of the upper extremity denoted that the destruction of ganglion cells was not so great as the first symptoms indicated. It was in this way that the speaker accounted for the very gratifying partial recovery which the patient had made. Although for several days after the accident, the upper extremities seemed paralyzed, a condition indicating very profound interference with the peripheral motor nerves, the rapidity of recovery showed that they were encroached upon, not destroyed.

It seemed to him that there were many factors in the case that spoke against the diagnosis of peripheral multiple neuritis, should such a diagnosis occur to one. The absolute symmetry in distribution of the paralysis, the absence of all sensory accompaniments, the absence of tenderness on pressure of the mixed trunks, and the mode of development, perhaps more than anything else, were against such a diagnosis. It was, perhaps, not so easy to differentiate acute poliomyelitis, but even that condition, the speaker thought, might be eliminated, considering the onset, the course, and the termination of the disease.

Dr. William Stevens then read a paper, entitled

NERVOUS AFFECTIONS OF THE STOMACH.

The author claimed that organic lesions of the stomach were an exception in cases presenting symptoms of stomach disorder. Functional troubles, however, were very common, and most of these were of reflex nature and the result of some organic affection located elsewhere in the body. A number of cases were reported to substantiate the position taken by the author.

Dr. J. H. Fruitnight, in discussing the paper, said that the point made by the author of the paper is frequently exemplified in the cases of children. Many affections ascribed to the stomach are really neuroses. Such cases require proper and carefully administered nourishment. When the stomach disorder has reached a still more advanced stage, rest of the organ is indicated. Food *per os* should therefore be withheld temporarily.

SARCOMA OF THE APPENDIX.

Dr. Robert A. Murray reported the following unusual case: The patient was a boy, six years of age, whom he had seen at ten o'clock at night on May 4, 1896, in consultation with Dr. William E. Forest of this city. There was no family history of malignant disease. The boy was poorly nourished but very active, and a year previous he had fallen from a second-story window, without, however, sustaining any serious injury. A month before the speaker saw him, the boy was attacked with pain in the right hypogastrium. A tumor was discovered in this region and a diagnosis of appendicitis made. Under rest and the application of ice the inflammation disappeared, although some hardness was left in this region.

When the patient was first seen, he had been ill for about a week. Pain was marked, the abdomen distended and tympanitic, the knees drawn up, and a tumor could be felt extending a little inside the spine of the ilium, toward the navel. There was no fluctuation. The bowels had been obstinately constipated. His temperature was 103.5° F., and pulse 110 and steady. Vomiting was not marked. He was seen again the next morning. In the meantime, ice had been applied to the region of the tumor, and he had been given repeated doses of a saturated solution of sulphate of magnesia, the latter resulting in a free movement of the bowels. The temperature was still 103.5° F., and the abdominal tenderness well marked. The patient's condition was so low that immediate operation was deemed necessary. An incision was made in the right hypogastrium and, upon opening the abdomen, a large mass was found upon the side of the appendix and involving the intestine. This mass was as large as a fist, easily broken down with the finger, and involved the intestine to the extent of three inches opposite the attachment of the mesentery, the latter being thickened and agglutinated to other portions of the intestine by exudation. The patient's condition was so desperate that no attempt at resection was made, and the gut was simply brought up in the wound, opened, and stitched there after flushing the parts with hot salt solution.

Immediately after the operation, the pain and vomiting ceased, and the tympanites disappeared. By evening the temperature went down to 100° F. Feces and a large quantity of gas were passed through the opening in the gut. The wound was dressed each day with oakum after irrigation with boric acid solution, and zinc ointment was applied to the edges of the wound in order to prevent irritation. The temperature went down to normal within a week, and in the course of a month the patient was well enough to be lifted to a sofa. He made a good recovery, the wound remaining open and feces being passed both through the wound and by rectum. The boy grew stronger, and was able to come to the speaker's office in August. At this time the wound was still open, and a marked induration about its edges, which had first been noticed in July, persisted. This induration increased rapidly, and to such an extent that it obstructed the bowel. The boy became very much emaciated and finally died in December, about eight months after the operation. Unfortunately, no autopsy was obtained.

Sections of the tumor had been given to Dr. Grauer, who pronounced the disease to be round-cell sarcoma, involving the entire section of the bowel and the mesentery, and declared it to be very malignant, and sure to recur. Slides were exhibited.

The case was interesting on account of the involvement of the appendix with the sarcomatous growth, and because of the rapid improvement which followed the operation. The latter undoubtedly prolonged the child's life for eight months. Any attempt at resection of the intestine would certainly have proved fatal on account of the desperate condition of the patient, and at no time did his health or the state of the wound give promise that further interference would be well borne.

In the discussion which followed, DR. WILLIAM VISSMAN, who was present by invitation, and had examined the slides, said that he doubted the evidence of malignancy as shown by the microscopic specimens.

REVIEWS.

WATER AND WATER SUPPLIES. By JOHN C. THRESH, D.SC., M.B., Etc. London: The Rebman Publishing Co. Philadelphia: W. B. Saunders. Pp. xvi–438. 1896.

TO quote the author: "The main object of this little work is to place within the reach of all persons interested in public health the information requisite for forming an opinion as to whether any supply, or proposed supply, is sufficiently wholesome and abundant, and whether the cost can be considered reasonable."

The writer, who has had large experience in submitting plans for the furnishing of wholesome water for scattered populations in rural districts, points out the importance of wholesome water supplies. Our sanitary inspectors in rural districts might learn a great deal by the careful perusal of the words of admonition which Dr. Thresh gives in regard to this matter in the preface of his work. Intended reforms might be modeled on the lines of the writer's suggestions, upon the remedies for the present method of well-water supplies from such wells as are supplied by filtration or percolation of surface or subsoil waters through surrounding strata.

For the purification of rain water the writer describes the ingenious rain-water separator of Roberts, in which the dirty water is separated from the clean. The use of water derived from soil or subsoil drainage, especially in such cases where contamination may easily result from surrounding dwellings or barns, and more or less easily possible, according to the prevalent geologic formation, is particularly dangerous from a hygienic point of view, the possibility of contagion in such cases being raised to a maximum. A large part of epidemics of disease have been traced to such sources, and the necessity of the careful inspection and immediate remedy of these conditions can only be most strenuously impressed upon State Health officials and examiners.

The physical, chemical, and bacteriologic examinations of a water must be made before it can be used for potable purposes; in fact, it would be unwise to accept a water for drinking purposes unless it answered certain requirements when subjected to all of these methods of examination, one method alone not giving us sufficient data to enable us to judge of its purity.

The method of examination, the interpretation of the analysis, and the disorders and diseases resulting from the use of impure and unwholesome waters, are carefully treated in this work. The filtering of all waters, in which there is a possibility of contamination, is recommended, and the employment of domestic filters is especially considered.

The rest of the work is devoted chiefly to engineering facts and plans, the part cited above being most useful to the medical profession. On the whole, the book, which is excellently indexed, may be recommended for careful perusal to any one in search of information upon this subject.

THE SPAS AND MINERAL WATERS OF EUROPE. With Notes on Balneotherapeutic Management of Various Diseases and Morbid Conditions. BY HERMAN WEBER, M.D., and F. PARKS WEBER, M.D. London: Smith Elder & Co., 1896.

THIS handy and compact volume of nearly 400 pages is one of the best of its kind that we have ever had the pleasure of reviewing. After looking it through with some care we are gratified at being able to state that the authors have had a most laudable end in view in its preparation, and that the book bears no earmarks of personal or corporation interests, as so many "guide-books" that have gone before have done. It is intended to supply, and does supply, some knowledge of the spas of Europe, the method of treatment adopted there, and the morbid conditions which are most likely to be cured or ameliorated by them.

When one recalls the exodus of American citizens from these shores every summer, compared with which that from Egypt was naught, and if he bears in mind the fact that a considerable number of these seek renewal of health at some European spa with the tacit consent or at the suggestion of their medical advisers, it is readily apparent that the latter should know something whereof he recommends. If one would obtain such information we heartily recommend this little volume. The chapter on balneotherapeutic management is most satisfactory, considering the small amount of space devoted to it. The value of the book is enhanced by a bibliographic table and by a comprehensive index.

ORIGINAL ARTICLES.

EARLY DIAGNOSIS AND EARLY NEPHRECTOMY FOR TUBERCULOSIS OF THE KIDNEY.[1]

BY WILLY MEYER, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

AT the annual meeting of the Medical Society of the State of New York, January 29, 1896, I read, by the kind invitation of its president, a paper entitled "The Early Diagnosis of Tuberculosis of the Kidney."[2] My remarks were based on the cystoscopic examination of two male patients who evidently suffered from primary renal tuberculosis in its early stage. The examinations were made by me in 1892 and 1893, *i. e.*, at a time when we were not yet in possession of a useful instrument for catheterizing the ureters. The correctness of my diagnosis, to my regret, could not be demonstrated by producing the pathologic specimens. Both men refused to accept my advice to have nephrectomy performed at once.

By way of reviewing the principal facts laid down in the article mentioned, I would here state the following: It is only the chronic form of tuberculous inflammation that interests the surgeon. The other form, acute miliary tuberculosis, belongs to the domain of internal medicine. The chronic tuberculous inflammation of the kidney is always at first unilateral and descends from the one kidney into the bladder (infecting on its way the ureter), and involves in the beginning one side of the latter organ only. In many instances of commencing renal tuberculosis this one organ, the kidney, alone is attacked by the deleterious inroads of the *bacillus Kochii*, while the lungs, intestinal tract, bones and joints, are absolutely healthy. Considerable time always elapses before the prostate, with the rest of the genital system and the other kidney, become affected.

With reference to diagnosis, I maintained that it was absolutely necessary that the general practitioner should make or have made a very careful analysis of the urine, whenever, in a formerly healthy person, a painful and frequent micturition sets in suddenly, with or without intermittent renal colic, while a formerly transparent urine becomes turbid by the admixture of mucus, pus, or even blood. In such cases one should not invariably think of the presence of a renal calculus, but also of the possible presence of primary renal tuberculosis. The analysis of the urine should include microscopic examination for tubercle bacilli.

If there be suspicion of tuberculous disease, a negative result should not be accepted as final, but the examination should be repeated a number of times. It has been a great help, according to my experience in such cases, to have the patient collect in one large bottle the urine discharged during twenty-four hours, and at the end of this time to shake up the sediment well and fill a six- or eight-ounce bottle with an average specimen. The analysis of this specimen forms the basis for conclusions with reference to the health or disease of one or both kidneys. If tubercle bacilli are found, the diagnosis of tuberculosis of the urinary system is settled; if they are not detected, microscopic specimens should be taken from that sediment which had formed in the entire amount of urine collected within twenty-four hours. Should the microscope fail, after repeated trials, to prove the presence of the bacilli, it will be well to inoculate a rabbit by injecting some of the sediment into his pleural or peritoneal cavity. The use of Koch's tuberculin, which, after injection makes tubercle bacilli appear in the urine of patients suffering from renal tuberculosis (Czerny), cannot be advised on account of the occasionally injurious effect of these injections. The best means, however, for clearing up a doubtful case, and the only one by means of which an exact diagnosis can be made with reference to the primarily affected part of the uropoietic system, is cystoscopy in combination with catheterization of the ureters.

In the article mentioned above I stated that if after repeated search tubercle bacilli were not found in the urine of a patient in whom the presence of tuberculous disease was suspected, the cystoscope would settle the diagnosis. I said: "On viewing the interior of the bladder, the cystoscopist perceives an absolutely healthy surface of the vesical mucous membrane and one perfectly normal ureteral opening. The mouth of the other ureter, however, is injected, and a number of circumscribed, clearly defined, inflamed areas of mucous membrane can be seen between it and the slightly hyperemic trigonum, leaving the interposed tissue unchanged in appearance; and thus one recognizes with marvelous and astonishing clearness the enemy's steps in a hitherto uninvaded field. I could not compare this picture better than to liken it to foot-prints in the freshly fallen snow. No other disease of the bladder or kidney with which I am acquainted presents a similar cystoscopic appearance."

---

[1] Read before the Surgical Section of the New York Academy of Medicine.

[2] MEDICAL NEWS, March 7, 1896.

From this cystoscopic picture alone, I should venture to make the diagnosis of primary tuberculosis of one kidney, so much more, if intermittent, frequent, and painful micturition be the principal symptom. In a case of non-specific pyelitis or pyonephrosis the patient will pass his urine every four or six hours, even if one-third of the whole amount is pure pus. In cases of gonorrheal affections of the kidney, where the pathologic process has ascended, it naturally has passed the vesical viscus, and there first produced a gonorrheic catarrhal inflammation. If a patient with renal tumor be submitted to a cystoscopic examination early, say after the first attacks of hematuria, the bladder will be found normal throughout; that is to say, assuming that infection had not been previously carried into the bladder by catheterization with insufficiently disinfected instruments, which could have set up an artificial catarrh. Should this have occurred, the picture will be blurred. It cannot then be expected that cystoscopy can be performed with success and satisfaction. From this point of view we cannot too strongly insist upon the primary use of the cystoscope. Not in every case of primary renal tuberculosis that is subjected to an early cystoscopic examination, will the clear, unmistakable picture, as above described, be seen. Those clearly defined, circumscribed inflamed areas of the vesical mucous membrane between one ureteral opening and the internal urethral orifice, may be missed. Only the site of the mouth of one ureter may be inflamed and swollen; or, besides this phenomenon, and that in somewhat more advanced cases, a few disseminated, injected areas or superficial small ulcerations will be found in the fundus of the bladder behind the ureteral fold or on the lateral vesical wall corresponding to the affected side.

What I mean to emphasize here as an established fact is this: A rather recent, sudden, or slow appearance of painful or frequent micturition in a hitherto healthy subject who had not been infected with gonorrhea; concurrent with this, permanent, or more especially intermittent, voiding of a turbid urine with or without blood; on cystoscopic examination, a perfectly healthy bladder with only one ureteral opening clearly inflamed and swollen means "primary tuberculosis of the respective kidney." And this diagnosis can be made with propriety even when tubercle bacilli are not found. The cystoscopic diagnosis will be confirmed if circumscribed inflamed areas are seen unilaterally in the bladder, either between the inflamed mouth of the respective ureter and the trigonum, or behind or to the side of the ureteral opening. It is, of course, possible that if a patient's bladder be inspected immediately after the first onset of the above-described renal symptoms, the secondary vesical symptoms have not yet had sufficient time to properly develop. Judging from what my experience has shown me, I should say that the secondary infection of the respective ureteral opening would appear very early in primary tuberculosis of the kidney, that is to say, within about four to six months. It is understood that nowadays catheterization of the ureters and separate drainage of the secretion of each kidney, with separate analysis of the urine collected in this way, is to be added to the cystoscopic examination in order to corroborate and still further define the result of the cystoscopic diagnosis.

I have mentioned above, that the surgeon must also exhaust all the means at his disposal to test for the presence of tubercle bacilli.

The following case which came under my care through the kindness of Dr. Elizabeth Cushier, Attending Physician to the New York Infirmary, will well illustrate the correctness of the statements just made:

Mrs. E. K., forty-six years of age, widow, married when twenty-five years old. Had had four children; no miscarriages. Youngest child two and a half years old. Two sisters died of phthisis. Husband was killed by an accident in the fall of 1894; had always been a strong, healthy man. Since his death the patient had worked hard to support her family. In August, 1895, her skull was fractured by a brick which fell from a building. She was treated at Bellevue Hospital for six weeks, but was not trephined. Up to that time she had not had urinary trouble or other symptoms of disease. She soon began to complain of frequent micturition, accompanied by lancinating, burning pain. From that time these symptoms continued to increase in severity, with intervals of comparative comfort, the pain being noticed before, during, and after the act of micturition. The latter was very frequent, hourly, half-hourly, and sometimes even every fifteen minutes. She also had pain in the pelvis, bearing-down sensations, backache, and nearly constant headache. She did not feel able to work, was weak, and did not sleep well. Appetite was fair, and bowels generally regular. The patient attributed most of the bladder symptoms to the fracture of the skull. She had consulted a physician in reference to the pelvic symptoms (she also suffered from leucorrhea), and he sent her to the New York Infirmary for observation and possible repair of a lacerated cervix. She was admitted to the Infirmary in April, 1896.

Examination showed great sensitiveness of the bladder to pressure through the vaginal wall; also, behind the cervix high up in the right vaginal fornix.

The cervix was lacerated, and the uterus rather large, but in a normal position. The urine, which was frequently examined, was generally found to be faintly acid or neutral, and slightly turbid. Specific gravity, 1014 to 1016. Odor normal. After filtration some albumin was found, but no sugar. The microscope demonstrated many pus cells, some of them broken down, and very few blood cells. There were no triple phosphates or casts. On one occasion the urine was quite clear and gave no reaction for albumin. Pulse 72 to 80; no rise of temperature (only twice it rose to 100.2° F.). Heart and lungs normal. Besides daily irrigation of the bladder with a normal salt-solution, the patient received some gynecologic treatment. There were several exacerbations of bladder pain and frequency of micturition, lasting several days. At such times the patient passed a small quantity of urine every half hour or hour, day and night, and complained of severe pain; between the exacerbations the pain was much less severe, but always present to some degree, and urination occurred seven or eight times a day. Amount of urine thirty to forty-five ounces daily.

Because of the continued presence of pus in the urine, the bladder symptoms, and the unabated sensitiveness to pressure on the bladder, especially at a point corresponding to the entrance of the right ureter, Dr. Cushier kindly sent the patient to me for a cystoscopic examination. On June 5th I performed the latter at my office, in the presence of Drs. Elizabeth Mercedes, Pathologist to the New York Infirmary, and Marian D. McDaniel, of the Infirmary staff. Contrary to my usual (routine) practice in these cases, namely, first, to make a careful general examination of the patient, and also a chemic, microscopic, and bacteriologic analysis of the urine, for several reasons, I introduced the cystoscope at once, without these previous examinations, and found the following most interesting condition: The entire bladder, the left ureteral fold, and the mouth of the left ureter were perfectly normal. The latter receded and protruded at intervals, and gave exit, as it appeared, to perfectly clear urine. The trigonum was very slightly injected. Corresponding to the mouth of the right ureter a uniformly purplish-red, somewhat elevated, spot of about the size of a ten-cent piece was seen. It presented an irregular surface, had a number of ecchymotic spots, and was covered here and there by white flakes of mucus. It did not move with the expulsion of urine. Its border line was rather ragged, but very distinct. The surrounding surface of the bladder was absolutely normal, not injected. No other spot of the interior surface of the bladder appeared to be diseased. The picture was striking, and, according to my cystoscopic experience, so characteristic of tuberculous disease that I at once asked the doctors present whether search for tubercle bacilli had been made in the specimens of urine. Receiving a negative reply, further examination was stopped for the time being.

In a subsequent search, Dr. Mercedes found the bacilli. Dr. Fred. E. Sondern also made an analysis of the urine, at my request, and reported the presence of a very small amount of blood, a moderate amount of pus and mucus, some hyalin and finely granular casts, numerous cells of the superficial and middle layers of the bladder (also intact aggregations of the same), some groups from the renal pelvis, and several groups of tubercle bacilli.

On June 18th the patient again came to my office, for catheterization of the ureters. Casper's instrument was used, and the left ureter was easily entered. The urine was perfectly clear, light amber in color, and 12 c.cm. was collected in ten minutes. The attempt to introduce the tiny catheter into the right ureter was difficult, but soon successful, in spite of the indistinct appearance of the orifice. It could be done only by carefully and repeatedly testing the inflamed area described above with the tip of the ureteral catheter. This caused a small hemorrhage. Suddenly the catheter slipped in, but it could be pushed forward a very short distance only. An impassable resistance was met with. There evidently was a stricture about three-fourths to one inch above the orifice. As further manipulations proved to be of no avail, and urine did not flow through the catheter, the instrument was removed and the bladder washed out and cocainized for a second time. A small blood clot was found in the eye of the catheter. A second and, later, a third attempt was made to complete the separate collection of the urine descending from the right kidney, but my efforts were unsuccessful, the stricture precluding success. Yet the work had not been done in vain. I had for examination and comparison the bladder urine and the specimen separately collected from the left kidney. If the latter proved healthy, the conclusion was absolute that the right kidney was the seat of the disease, and this on the simple reasoning that the bladder urine had shown evident symptoms of renal disease, and cystoscopy had proved the bladder, except the right ureteral orifice, to be in a healthy condition.

The specimen of urine collected from the left kidney was submitted to Dr. Sondern for examination. He reported that it showed absolutely nothing abnormal; that tubercle bacilli could not be found on repeated search; and he concluded that the left kidney was normal. Thus, the separate analysis of the specimens of urine fully corroborated the clinical diagnosis made at my first cystoscopic examination: primary tuberculosis of the right kidney, with secondary, still localized, involvement of the bladder. Nephrectomy was decided upon and performed, with the kind assistance of Drs. Gertrude B. Kelly and Eleanor B. Kilham, on June 30, 1896, at the Infirmary. The kidney was found to be comparatively large; it was situated rather low. The wound was partially closed by suture, partially packed with aseptic gauze. The pedicle was secured by an elastic ligature. The patient stood the operation very well, and her recovery was uneventful. The urine voided on July 1st, the day after the operation, was perfectly clear and light amber in color. It was faintly acid, and did not contain albumin or sugar. Micturition was almost painless, and less frequent by far than before the operation.

I owe thanks to Drs. Kelly and Kilham, and to the members of the house staff of the Infirmary. To their faithful after-treatment I feel that the patient's rapid and uneventful recovery is largely due.

The specimen obtained is of great interest.

Macroscopic Examination.—Kidney measures 11 x 7 x 6.5 centimeters. Surface slightly lobulated, as in fetal state. Scattered over the entire surface are tiny elevations from 2 to 5 mm. in diameter. Some of these are clear and translucent, evidently small cysts, while others are opaque and firm.

The capsule strips off readily, leaving these intact beneath.

A considerable portion of the hilus has been cut away, exposing an irrgular cyst-like cavity about 2 cm. in diameter. The wall is thin and quite smooth on the inner side. The cavity extends to within nearly 2 mm. of the surface. (Beginning tuberculous pyonephrosis.)

Upon section through the cortex, the kidney is found healthier at its upper end. Here the pyramids are well marked; at the lower end not. Here and there, especially throughout the cortical layer, are seen the same opaque plugs as noted on surface. In the lower half of the parenchyma of the organ, near the cortex, is found an abscess cavity of about double the size of a pea. It is irregular, and filled with thin pus.

Microscopic Examination.—Section through cyst wall: The outermost layer is of connective tissue, poor in nuclei. Beneath this is a marked infiltration, with lymphoid cells, and also free blood in the tissue. Malpighian tufts show partial or complete hyaline degeneration. The inner edge is formed of degenerated tissue, but no tubercle tissue is seen anywhere.

Section from cortex: The small-celled infiltration is more general; changes in Malpighian tufts the same. But here we find large and small areas of the typical tubercle tissue. In places this is quite broken down, and corresponds to opaque points seen on the surface and through the cortex.

Diagnosis.—Diffuse tuberculosis of the kidney, with formation of cysts. Small areas of cheesy degeneration. (Report from Pathological Record of New York Infirmary. Signed, E. Mercedes, Pathologist.)

To-day the wound is firmly closed, and the patient has gained in weight, in spite of her daily hard work. She voids normal, healthy urine about every four or six hours during the day, without any trouble or pain, and during the night voids none at all.

As far as the influence of the removal of the diseased kidney upon the commencing vesical tuberculosis is concerned, it seemed to be not only of interest, but of importance (mainly with reference to clinical experience) to perform cystoscopy once more. It had to be decided, as far as one single case can show anything, whether early extirpation of a tuberculous kidney can cure a beginning bladder affection *per se*, that is, without any further local treatment; or, whether tuberculous, though localized, infection of the bladder, having once occurred, will persist, although the continued reinfection from above had been rendered impossible; or, thirdly, whether, when the bladder has once been infected, the disease will spread and involve the entire organ.

Four months after the operation I, therefore, once more examined the patient's bladder at my office in the presence of Dr. McDaniel. I was astonished to see that the formerly inflamed area had entirely disappeared. The right ureteral opening was clearly visible, and the tissue surrounding it just the least bit injected. The vesical wall in its immediate neighborhood appeared normal. Thus the patient's cell energy had gotten rid of a beginning tuberculosis of the bladder, simply by the radical elimination of the continuously reinfecting primarily diseased focus. I believe this speaks for itself.

In perusing the literature on this subject, I have been able to find but one case where, by virtue of an *early* established definite diagnosis of primary tuberculosis of one kidney, nephrectomy was performed with the same effect and success as in the case here reported. It is the well-known case of L. Casper of Berlin, published in the *Berliner Klinische Wochenschrift* for April 27, 1896. It very much resembles that of my own. Briefly stated, it is as follows:

The patient, a woman aged forty-two, with negative family history, while suffering from a cold, was suddenly affected with frequent micturition and turbidity of urine. Soon intermittent pain in her right loin, together with an annoying sense of abdominal tension, was added to the other symptoms. Irrigation of the bladder only aggravated the trouble. Six months after the onset of the disease she came under Casper's care. Loss of weight up to that time amounted to six pounds. She urinated about every three hours in the day time and two or three times during the night. The urine was slightly turbid and of acid reaction. The specific gravity was 1018. It contained numerous pus cells, epithelial cells of the renal pelvis, and some albumin. There was no blood or casts. Bacteriologic examination revealed tubercle bacilli. Palpation of kidney and bladder negative. Upon cystoscopic examination the bladder appeared healthy throughout. The vessels of its mucosa were clearly defined. The left ureteral opening was normal In the situation of the right ureter, whose opening could not be seen, was a diffusely injected, slightly elevated area. Clear urine spurted at intervals from the normally moving left ureteral mouth. The reddened spot at the usual site of the right one was immovable. Now and then a whirl of fluid emanated from it. The observer's eye was unable to distinguish any change in the translucidity of the latter. Two days later the ureters were catheterized. The left kidney discharged perfectly clear, normal urine. It was difficult to enter the right ureter. After a number of unsuccessful attempts the instrument suddenly slipped into the canal and was readily pushed forward. The urine thus obtained resembled the bladder urine, being turbid, slightly purulent, and albuminous. The amount of its albumin was in excess of that found in the bladder urine. Tubercle bacilli could not be demonstrated.

They were found, however, in another specimen which was drawn from the right kidney three days later. Diagnosis: Tuberculosis of the right kidney with circumscribed involvement of the bladder.

Some time later Professor Von Olshausen of Berlin performed nephrectomy. The surface of the kidney was covered with tuberculous nodules, and two cheesy foci were found in the parenchyma. The patient recovered. The urine rapidly cleared up and her pain disappeared.

By a peculiar coincidence, both patients, Casper's and my own, were female subjects. I wish to emphasize that this exact diagnosis could as well have been established if both had been males.

Meanwhile other authors have perhaps been similarly fortunate in making such an early definite diagnosis of this, in its ultimate course always deadly, disease. If so, I trust they will publish their interesting experiences. A multitude of similar successes must convert doubtful minds in the medical profession and make them draw this important conclusion: *In obscure urinary diseases always have an exact analysis made with the help of all modern means, and that as early as possible.* If this has been done beyond a doubt, do not let us avoid the logical consequence, *timely radical operation.*

Every one of us has seen over and over again tuberculosis of the urinary tract in its later stages. I need not describe its terrible symptoms. Surely the disease is much more frequent than the general practitioner seems to believe. Glancing over my records of this year, I find that I was able to definitely diagnose descending unilateral renal tuberculosis, with subsequent involvement of the bladder in a comparatively early stage, in five patients. Almost every one of these, however, had passed the border line where nephrectomy alone could have effected a permanent cure. In a number of them the additional total extirpation of the diseased ureter (a decidedly more serious operation than simple nephrectomy) would have been indicated. Perhaps a longer stay in a warm climate, with proper general regimen, local vesical treatment, etc., might also have so far improved one patient that we might later have been able to speak of a cure. But what an amount of sacrifice is required to save such a patient's life! How often will recovery be impossible because he cannot afford to carry out our orders; meanwhile, how often in the male subject will an ascending affection of the other kidney and the absolutely incurable involvement of the genital sphere have taken place.

Happy may we be, therefore, that the improved instruments at our command to-day have placed the means at our disposal to make an early exact diagnosis, on the basis of which we can do ideal surgical work. Every case thus saved from a slowly wasting disease, dreadful in its duration, its tortures, and ultimate end, surely means a triumph of modern surgical diagnosis and therapy!

THE CHEMISTRY OF GALL-STONES, WITH SPECIAL REFERENCE TO THEIR MODE OF ORIGIN.[1]

By R. H. CHITTENDEN, Ph.D.;
OF NEW HAVEN;
PROFESSOR OF PHYSIOLOGICAL CHEMISTRY IN YALE UNIVERSITY.

The biliary calculi, or concretions, which are so frequently formed in the gall-bladder, and in the intrahepatic bile-ducts, may be divided on the basis of their chemical composition into three main groups, *viz.:* (*a*) those which are composed in great part of cholesterin; (*b*) those whose chief constituent is bile pigment, combined with calcium; and (*c*) those composed mainly of calcium carbonate and phosphate. In man, however, we have to deal chiefly with calculi containing a large predominence of cholesterin, with some admixture of pigment and calcium, *i.e.*, the so-called mixed cholesterin calculi; although occasionally nearly pure cholesterin stones are found, and, on the other hand, nearly pure pigment-calcium calculi may occur. A so-called cholesterin calculus, however, invariably contains some other material—at least in the nucleus—the largest proportion of cholesterin ever found in a calculus being, I believe, 98.1 per cent., while the minimal amount in a true cholesterin calculus is about 64 per cent. In the gall-stones of oxen cholesterin is sometimes wholly absent, while as much as 45 per cent. of bilirubin may be present, *i.e.*, in a typical pigment-calcium calculus.

In most cases the nucleus of the gall-stone is composed of the insoluble combination of bilirubin, or a related bile pigment, with calcium or lime. Less commonly, the nucleus appears to consist of a crystallin mass of cholesterin, with some mucus, while occasionally some foreign substance may serve as the center around which the concretion forms. According to Naunyn, the nucleus of many gall-stones is made up of spheres or warty masses of calcium carbonate.

It is thus evident that in considering the chemical composition of gall-stones we have to deal mainly with three classes of substances, *viz.:* cholesterin or cholesterins; bile-pigments, chiefly bilirubin, combined with calcium; and certain mineral salts, especially calcium carbonate and phosphate. Cholesterin, bilirubin, and calcium salts are all normal constituents of human bile, and we may profitably consider for a moment some of their peculiarities as an aid to a better understanding of their presence in gall-stones.

---

[1] Read before the New York Academy of Medicine, April 15, 1897.

Cholesterin, when pure, is a white crystallin substance, more or less waxy, lighter than water, readily soluble in warm alcohol, also in ether, chloroform, benzol, and other like solvents, but insoluble in water. Although it has many of the physical properties of a fat, it cannot be classed with the fats since it is non-saponifiable, and contains within its molecule neither fatty acid nor glyceryl radicles. In view of its peculiar solubility we may well inquire how it is that cholesterin exists dissolved in normal bile? As already stated, it is wholly insoluble in water, and also in aqueous solutions of neutral salts, but the salts of the bile acids—sodium glycocholate and taurocholate—exert a solvent action upon the substance, and it is in virtue of these constituents, aided perhaps by the soluble soaps and neutral fats, which are likewise present in bile, that the cholesterin is held in solution. The extent of this solvent action is indicated by some experiments made by Happel, who found that aqueous solutions of sodium glycocholate and taurocholate—0.2 to 2.5 per cent. in strength—are capable of holding in solution at the body temperature an amount of cholesterin equal to one-tenth the weight of the bile salt. Presumably, any concentration of the cholesterin beyond this point would be attended by its separation or crystallization.

The amount of cholesterin contained in human bile varies quite noticeably with the length of time the bile remains in the gall-bladder. Thus, as the recent analyses of Hammarsten[1] show, so-called "liver bile" flowing directly from the liver, contains 0.048 to 1.160 per cent. of cholesterin, while "bladder bile" may contain as much as 0.986 per cent. of the substance. This apparent increase in the content of cholesterin attendant upon the sojourn of the bile in the gall-bladder is not necessarily due, as might at first sight appear, to an outpouring or secretion of cholesterin from the mucous membrane of the bladder, but is the result of a general concentration of the bile attendant upon an absorption of water and of diffusible salts. This absorption of water with consequent concentration of the bile is not due, according to Hammarsten, to a simple process of diffusion, but is the result of a specific activity on the part of the epithelial cells of the mucous membrane by which water and soluble chlorids are removed. Hence, when from any cause bile is retained within the living gall-bladder for any great length of time, this process of absorption leads to a very great increase in the concentration of the fluid. Thus, while human "liver bile" rarely contains more than 3.5 per cent. of solid matter, "bladder bile" may contain as much as seventeen per cent. of solids. That this increase in solid matter is due only in part to secretion of mucous material from the walls of the gall-bladder is evident from the proportion of bile salts in the two cases. Thus, while liver bile seldom contains over 1.8 per cent. of glycocholate and taurocholate, bladder bile may show nearly ten per cent. of these salts. It is thus manifest that the increased amount of cholesterin found in bile which has stood for some time in the bladder can be wholly explained on the ground of growing concentration, due mainly to the withdrawal of water. Now, in this connection it is to be remembered that stagnation of bile in the gall-bladder is generally considered as a primary condition in the formation of gall-stones, that anything which tends to hinder the flow of bile favors the formation of biliary calculi, and the above facts certainly lend favor to this view. The mere concentration of bile, however, with its consequent increase in the percentage of cholesterin, does not necessarily imply that a crystallization or separation of this substance will occur, although it does follow that the conditions are thereby made more favorable for such separation. Thus, if bile is concentrated outside of the body by heat, there is no noticeable separation of cholesterin, no formation of concretions of any kind, even though the fluid be allowed to stand until putrefaction is well under way. Evidently, certain other influences, aside from mere concentration, are needed to incite the formation of a calculus.

We may next inquire what is the primary origin of the cholesterin found in the bile? On this point there are two views. One is that the liver simply separates from the blood flowing through it the cholesterin contained in this fluid, passing it over to the bile; while the other view, held especially by Naunyn, is that the cholesterin is of local origin, being formed chiefly by changes taking place in the epithelial cells of the mucous membrane of the gall-bladder. Now it is a well-known fact that cholesterin is widely distributed throughout the body, that it is present in large amount in nerve tissue, and is apparently contained in all animal cells in small amount. This latter fact implies that it is a constant product of cellular activity, doubtless coming from the metabolism of the cell protoplasm. Further, it is constantly present in the blood, both in the blood-serum and in the corpuscles, existing there wholly, or in part, as a cholesterin-ester. Unquestionably, a certain amount of cholesterin is normally found in the liver, as a product of the chemical changes going on in that organ, but its presence in the bile is to be accounted for mainly on the ground that this is one of the channels through which it can be excreted from the body. It is apparently a waste product, and not being easily decomposable it is eliminated unchanged, or in a slightly modified form, through the feces, as well as in the secretions from the skin, and in the milk. As a constituent of the bile it has, so far as known, no function to perform; it is purely an excretion, not of the liver alone, however, but of all the cells of the body, its elimination taking place mainly through the bile, possibly because this fluid is best adapted for its solution.

---

[1] *Jahresbericht über die Fortschritte der Thierchemie für* 1893, p. 331.

As just stated, cholesterin is not readily decomposed, but in the case of man, according to the recent experiments of Bondzynski and Humnicki[1], a portion of the substance undergoes modification in the intestine, appearing in the feces as koprosterin; a body closely related to cholesterin, and apparently formed from it by the addition of hydrogen. In the intestine of herbivorous animals, as in the horse, the change is still greater, the cholesterin being transformed into a body known now as hippokoprosterin, a product representing still further reduction. In the dog, on the other hand, the cholesterin of the bile appears in the feces wholly unaltered. So far as known none of these modifications of cholesterin occur in gall-stones.

Naunyn's view that the cholesterin found in bile is wholly of local origin can hardly be accepted. It certainly cannot be true of the cholesterin present in normal bile, although it may possibly be true of the cholesterin contained in gall-stones. Thus, according to Naunyn, whenever there is a retardation, or arrest, of the flow of bile, the *bacillus coli communis* of the small intestine may migrate from its ordinary abiding place to the bile passages, and even to the gall-bladder where it sets up a peculiar catarrh of the mucous membrane. However this may be, it is probably true, as stated by Mayo Robson, that the appearance of gall-stones is always accompanied by catarrh which gives rise to thick, ropy mucus. In such cases, says Naunyn, the epithelial cells are found gorged with fat- or myelin-like material, which may protrude from the cell and float off in the bile. Addition of acetic acid to such masses is seen under the microscope to cause at once the separation of a magma of cholesterin crystals. The inference naturally is that the cholesterin is manufactured in the epithelial cell as a result of perverted metabolism, but it may be, as suggested by Von Noorden, that these cells simply take up cholesterin from the blood and then throw it out in masses. However this may be, it is noticeable, as a rule, that whenever a cholesterin calculus is formed there is a nucleus of bilirubin-calcium around which the cholesterin is deposited. What now controls the formation of this insoluble calcium compound?

The normal bile pigments, bilirubin and biliverdin, when uncombined, are wholly insoluble in water. In the bile, however, they are held in solution, in part at least, by the alkali salts of the bile acids. Bilirubin and biliverdin alkali are readily soluble in water, but when soluble calcium salts are added to such a solution the pigment is precipitated as a calcium compound. Now, although normal bile contains a small amount of calcium, there is ordinarily no precipitation of the bile pigment, because of the restraining influence of the salts of the bile acids. If, however, an excess of a calcium salt is present, then precipitation may occur, insoluble bilirubin-calcium or biliverdin-calcium being formed. Frerichs, you may remember, has pointed out that the mucous membrane of the gall-bladder secretes lime salts, these passing into the bile; he states, indeed, that he has frequently observed the mucous membrane incrusted with crystals of calcium carbonate. This latter salt, however, itself insoluble, cannot be very efficacious in promoting the formation of bilirubin-calcium so long as the bile is alkalin. There is a general impression that normal bile is a strongly alkalin fluid. In one recent book on the chemistry of bile it is stated that this fluid contains about 0.2 per cent. of sodium carbonate, together with a like amount of alkalin-reacting sodium phosphate. But this is far from the truth. Indeed, the recent experiments of Jolles, as well as experiments now being carried out in my own laboratory, tend to show that bile does not contain any sodium carbonate whatever, and that such alkalinity as it possesses is due to salts of far less potency. In fact, when tested with phenol-phthalein as an indicator, the bile of man as well as the bile of the dog, cat, sheep, pig, ox, calf, etc., reacts acid. By this I do not mean that free acids are present, but that the fluid really contains acid salts, such as the alkali-hydrogen phosphate, which, however, may react alkalin to litmus and some other indicators. Now, Frerichs, you may recall, assumed that when the bile became stagnant in the gall-bladder, the mucus or nucleo-albumin secreted by the bladder induced in some manner a decomposition of the salts of the bile acids by which the reaction of the fluid became acid. In this way the solvent action of the sodium glycocholate and taurocholate upon both cholesterin and bilirubin was removed, and consequently the cholesterin separated as such, while the bilirubin came down in combination with calcium. Obviously, as Gamgee states, this acid fermentation could not originate spontaneously, but presupposes the intervention of some active agent, possibly a pathogenic organism of some kind. Further, Frerichs believed that not only must there be a pronounced stagnation of bile within the bladder, but, in addition, the coöperation of certain elements associated with catarrh of the lining membrane was required for this reaction to take place. Especially suggestive in this connection is the fact that gall-stones frequently contain in greater or less amount peculiar pigments that are rarely, if ever, found in normal bile; bodies such as the so-called bilifuscin and bilihumin which unquestionably originate from bilirubin or biliverdin as the result of changes, quite probably induced by microorganisms. Consequently, we see that the old-time views of Frerichs and the more modern views of Naunyn are not so greatly opposed to each other as would at first sight appear. In both cases the formation of the calculus is attributed to chemical changes having their primary origin in the epithelial cells of the mucous membrane of the gall-bladder and the intrahepatic ducts, associated with general stagnation of the bile. How far the production of cholesterin is dependent upon these changes is uncertain, but, assuming that the cholesterin found in gall-stones is in great part a product of the perverted metabolism of the epithelial cells, it is still evident that the initial changes leading to the formation of a biliary calculus are connected with the calcium and pigment, rather than with the cholesterin, since the nucleus of the stone is more generally composed of bilirubin-calcium. In this connection it is to be noted that the amount of calcium salts contained in the food, as well as the amount in the blood, is no criterion of the amount present in the bile. In other words, the proportion of calcium in the bile is not noticeably influenced by the amount ingested, which fact naturally suggests that the deposition of bilirubin-calcium must be connected with pathologic changes, as a result of which the normal calcium of the bile is transformed into insoluble combinations, or else, as appears quite probable, there is an increased secretion of calcium from the epithelial cells of the mucous membrane by which the formation of insoluble combinations is facilitated. With such compounds as a nucleus the crystallization of cholesterin is made possible, especially if the reaction of the stagnant bile is so altered that the sodium glycocholate and taurocholate are dissociated, and their solvent action upon the cholesterin overcome. Add to this the hypothetical production of cholesterin by the mucous membrane itself, and we have all the conditions favorable for a speedy production of biliary calculi.

---

[1] "Ueber das Schicksal des cholesterins im thierischen Organismus." *Zeitschr. f. physiol. Chem.* Band 22, p. 396.

With a calculus once formed, either in the gall-bladder or in the intrahepatic bile-ducts, the question naturally arises whether its removal can be accomplished by the action of any foreign solvent. To this I think we must give a negative answer, or to be more exact, I do not think we have any positive proof that its removal can be accomplished by this method. Indeed, it seems highly improbable. Far more plausible is the assumption that its solution may perhaps be brought about, in part at least, by agencies which tend to increase the flow and alkalinity of the bile, aided by an increase in the peristaltic contractions. Cholagogue effects, however, are not readily obtained. Indeed, the most recent experiments of Stadelmann and his coworkers in Germany, as well as the experiments of Pfaff[1] in this country, tend to show that with the exception of bile itself, and possibly of sodium salicylate, there are no substances which act as true cholagogues. Thus, the supposed cholagogues, calomel, corrosive sublimate, rhubarb, podophyllin, turpentine, sodium benzoate, salol, etc., are practically inactive, and of little or no value in stimulating the secretion of bile. Quite different, however, is it with the salts of the bile-acids, for if these are introduced into the gastro-intestinal tract their absorption is speedily followed by an increased secretion of bile; and of bile rich in bile-salts with their solvent action on cholesterin and bile-pigment. Obviously, such a line of treatment could be pursued with safety only when there is a free outlet through the bile ducts.

THE INDICATIONS FOR SURGICAL OPERATIONS ON THE COMMON BILE DUCT.[2]

BY F. LANGE, M.D.,
OF NEW YORK.

OF all the achievements of surgical art, which, within the last two decades, have widened its field, principally through the influence of antiseptic and aseptic technic, there is no perhaps no single one that involves so much responsibility and requires so much painstaking labor as an operation on the deep gall ducts. It is necessary to bear this in mind and to be conscious of the difficulties and embarrassing complications which may arise during such an operation, in order to meet the exigencies of a given case, and to follow step by step the banner of clear indication; to desist in time from fruitless attempts, or, with tenacity and perseverence, to push forward in spite of all difficulties, until the desired end is achieved.

It is well nigh impossible, within the time allotted to me, to give an approximately thorough or exhaustive treatise of the subject of the surgery of the common bile duct; and I take the liberty of limiting myself to the question: Under what circumstances is surgical interference with the common duct in cases of gall-stone disease indicated?

---

[1] Pfaff and Balch. "An experimental investigation of some of the conditions influencing the secretion and composition of human bile." *Journal of Experimental Medicine*, vol. 2, p. 49.

[2] Read at a meeting of the New York Academy of Medicine, April 15, 1897.

Safe and absolute indications for operation exist only when we can foresee with certainty the further development of a morbid process. Is this the case with gall-stones in the common duct? Every practitioner knows that cases of protracted jaundice, due to obstruction of this duct by stone, will frequently end in spontaneous recovery. Jaundice may persist for years, unmistakable symptoms of an infectious process in the gall-duct system may be present, and still such patients may recover without surgical interference. As long as such possibilities exist, even as exceptions, it will be impossible to give general indications for operation. The latter, therefore, is dictated or modified, or contraindicated by the clinical history of each case. Individualization is of preeminent importance; from the clinical point of view, however, and for practical reasons, two large groups of cases may be subject to general consideration: Those in which pure obstruction is the governing feature, and those in which the obstruction is complicated by inflammatory and infectious processes.

Absolute obstruction to the flow of bile for a prolonged period of time, caused by stone in the common duct, is of rare occurrence. Frequently more or less bile will pass by the stone. In other cases, owing to an intermittent ball-valve action, as described and experimentally investigated by Dr. Fenger of Chicago, the stone, by its receding from the narrow opening, will allow of the intermittent free flow of the fluid. From the observations of reliable clinicians one may justly assume that quite a large percentage of cases in which gall-stones pass the common duct, do not present any distinct icterus at all. The mechanical lesion alone, therefore, as a rule, is comparatively well borne in uncomplicated cases of stone in the common duct, and it will depend largely upon the degree of obstruction, whether the damaging influences of stagnating bile are such that the removal of the obstructing cause by operation is indicated or not. The physician in charge ought to be aware, however, that long persistency of intense icterus diminishes the safety of surgical interference through the cholemic condition of the blood and the morbid tendency to bleeding. In cases of uncomplicated obstruction of the common duct, therefore, we may formulate the indication thus: They require surgical help before persistent cholemia has increased the danger of an operation to an unnecessary and undue degree; and though icterus alone may occasionally be well borne for a long time without serious impairment of the general condition, we must, with the onset of such, determine the exact indication for surgical interference. I have had the misfortune to lose three patients after operations on the gall-duct system from uncontrollable hemorrhage due to cholemia. One of them had been subjected to choledochotomy, one to cholecystenterostomy, one to cholecystotomy. All these patients presumably would have been saved if operation had not been delayed from month to month, after all possible useless remedies had been tried for the expulsion and dissolution of gall-stones. The character of the hemorrhage in such cases is that of capillary oozing, especially from the surface of the gall-duct system or from adhesions in the abdominal cavity. I once had the impression that the sudden relief from pressure on the surface of an overdistended gall-bladder had something to do with it.

The second group of cases of obstruction are those in which complications arise, either by an infectious process, when we have to deal with cholecystitis and cholangitis in their various degrees and after-effects, or by ulceration as the direct consequence of impaction. In the latter instance it is not so very uncommon for spontaneous recovery to occur, the stone or stones passing through the wall of a neighboring viscus. To eliminate these cases we might say that they admit of expectant treatment. If a large stone has once been passed per rectum; if there should be a repetition of the attacks we may fairly assume that stones will pass again spontaneously and the obstruction be relieved. As a rule, one assumes that stones of more than moderate size will pass by a perforative process. If, however, the symptoms of intense obstruction or progressive septic infection should become very marked, an operation may be imperative.

Infection sometimes presents a decided indication for immediate surgical interference. It manifests itself by the symptoms of acute fever with frequent chills. The skin is deeply jaundiced, and the gall-bladder may be distended and readily palpable, but this symptom is absent in cases in which the walls of the viscus have become thickened by a previous inflammatory process. Such cases of acute cholangitis should be operated on at once. The first indication is to relieve stagnation and tension, and this is done by cholecystotomy. Whether the obstruction of the common duct ought to be dealt with at the same time depends upon the general condition of the patient. These cases are exceptions, but they ought to be dealt with according to surgical principles.

By far the greater number of cases are of a chronic or subacute character. The presence of a stone or stones in the common duct will keep up a permanent irritation, and chronic infectious processes will gradately spread over the surface of the gall-ducts. Dilatation of the ducts, atrophy of the glandular liver tissue, cholangitis, pericholangitis, and finally liver abscesses, usually of the disseminated variety, will be the end stages of this morbid process. We must bear these possibilities and their unfavorable prognostic elements in mind, and realize that the removal of the obstruction and the bringing about of a free flow of the secreted bile is the only rational method of treatment. With our present experience with the technic, we may safely say that choledochotomy, in the majority of cases, is a difficult and tedious operation, which may tax to the utmost the resources of the patient, but its results usually are eminently favorable. Among my successful cases I have had several in which unmistakable symptoms of chronic cholangitis existed at the time of the operation, but gradually yielded after removal of the stones, and in the course of months resulted in complete *restitutio ad integrum.*

Let me mention here the valuable observation of Riedel, that a gall-stone in the common duct will occasionally be the cause of a chronic inflammation of the pancreas, and that in such cases we may be much in doubt whether the hard mass under the examining finger indicates a malignant growth of that gland or an inflammatory thickening. It is useless to emphasize the very different prognostic value of these two affections. To differentiate cases suitable for choledochotomy from those in which it is preferable to leave the stones *in situ* and to resort to cholecystenterostomy, would, I fear, lead me too far into the discussion of the purely surgical aspect of the question, and beyond the limits of the allotted time. Let me emphasize once more, that preservation of life and health in many cases of gall-stone in the common duct depends upon the proper time chosen for surgical interference.

DISTOMA HEMATOBIUM; DESCRIPTION OF A CASE.[1]

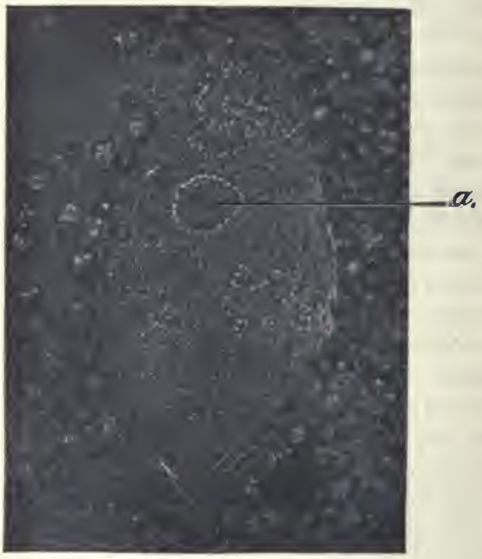
By FREDERIC E. SONDERN, M.D.,
OF NEW YORK.

THE distoma hematobium, discovered by Dr. Bilharz[1] of Cairo (1851) in the portal system, is generally named *distoma*, from the Greek δι for δις, and στομα, and should, therefore, not be called *distomum*, although Bilharz employed the latter term. Some years later, Cobbold[2] gave the species the name "Bilharzia," in honor of the discoverer; and other names, such as *gynæcophorus hæmatobius* (Diesing[3]), etc., have since then fallen into disuse.

An examination of one private library only, that of Dr. A. Jacobi, permits of the statement that "English and American text-books on medicine, urinary diseases, and clinical microscopy," are *not* unsatisfactory, as Dr. Brooks would have us believe, but, on the contrary, many offer lengthy, well-written, and well-illustrated articles which exhaust the subject thoroughly, in proof of which I refer to Harrison,[4] Roberts,[5] Cobbold,[6] Guillemard,[7] the English editions of v. Jaksch, and Ziegler, the works of Fenwick, Beale, Curtis, and Handford, as well as more than thirty-eight original articles scattered throughout English and American medical journals. A most excellent index of this literature has been compiled by J. C. Huber.[8]

The geographic distribution of the *Bilharzia*, according to Ruetimeyer,[9] includes not only the west coast, but also the east coast of Africa (Eyles[10]), particularly Egypt, where the most severe cases are observed, and Cape Colony. Wortabeh reports cases in Syria and Sicily. Blanchard does not credit the cases reported from Madagascar and Mauritius, believing them to be due to the *filaria sanguinis.* It is also doubted if the twelve cases reported by Hatch[11] *originated* in India. Nor can I find records of fully authenticated cases having originated in Arabia or Brazil, statements to the contrary notwithstanding. Hirsch emphasizes the occurrence of the parasite on the seaboard, and at the mouths of rivers, up to ten miles inland, in countries where it is endemic; Egypt seems to offer an exception to this.

FIG. 1.



Egg of the *distoma hematobium.* *a.* Beginning formation of stomach of embryo. Microphotograph × 430 diam. Zeiss apochromatic, 4 mm.

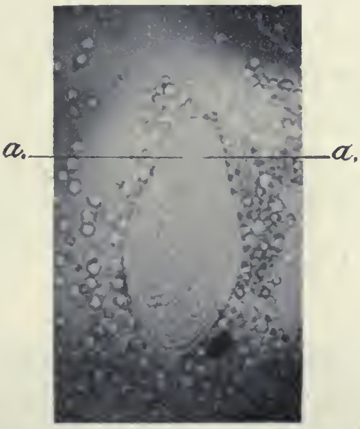
---

[1] The case here described is the same one mentioned in the *Medical Record* of April 3, 1897, by Dr. H. T. Brooks, who, I am told, did not see the patient but made an analysis of his urine.

Ruetimeyer concludes that the endemic origin of the disease has not crossed to the eastward of the Suez canal.

As to the etiology, Sonsino's[12] investigations during the summer of 1893 are now generally accepted, according to Ruetimeyer and others, and if so would antiquate the quotations from Lenharz. They would also allow the conclusion that the simple filtration of water, even if only through a cloth, is a sufficient prophylactic measure.

Fig. 2.



Egg of *distoma hematobium*. *a*. Development of duct on each side of embryonic stomach. Microphotograph × 230 diam. Zeiss apochromatic, 4 mm.

The anatomy of the *Bilharzia*, a unisexual trematode worm, has been carefully described even by the older authors, Fritzsch,[13] in 1888, adding more details. As these more recent descriptions are to be found in text-books they need no repetition here. Contrary to the quotations of Dr. Brooks, I would add that according to Fritzsch, the worms are oftentimes but half the length he states. They have but one sucker and one mouth, not two suckers. The female is taken up in the *canalis gynæcophorus* of the male for copulation, and, while remaining there for some time, is not *carried* there as was stated.

The pathologic anatomy of the condition in question is likewise of interest, and has been minutely described by Reutimeyer, to whose painstaking and original work I would refer. Contrary to Dr. Brooks' statement, Ruetimeyer and others have not been able to find pathologic conditions in the human spleen.

The following case, which is the same one referred to by Dr. Brooks under dates of March 20 and 25, 1897, has been under the continuous observation of Dr. A. Jacobi since March 22, 1897, with whom I have followed it daily since then. To him I am indebted for the careful and detailed examinations, and the privilege of reporting it. I repeat the clinical history on account of additional data.

R., male, thirty-two years of age. Born in Russia. Family history negative. General health always good. From 1885 to 1893 he resided in England. On December 15, 1893, he went by steamer, *via* Lisbon, Madeira, and Cape Town, to Port Elizabeth, South Africa, arriving on January 15, 1894. He resided there for six months. During this time he took frequent baths in the bay and river, and admits that he probably swallowed some of the water. At other times he drank both hydrant and spring water. His health was good, excepting one attack, of short duration, of severe pain in the region of the bladder, which radiated into both groins.

Leaving Port Elizabeth in June, 1894, he resided for the following six months in Kimberly, West Griqualand, during which time he was apparently well, with the exception of another attack of pain as above, without diarrhea. He also had a short attack of "fever." At the end of November, 1894, he left Kimberly for Cape Town, where he remained one week. Leaving the latter place on December 5, 1894, he proceeded by steamer, *via* Madeira and Lisbon, and arrived at Portsmouth, England, on December 26, 1894. He remained in London until January 5, and sailed from Southampton for New York on that day, arriving here on January 12, 1895. On January 15, 1895, three days after landing, he observed, for the first time, a small clot of blood at the end of micturition, without tenesmus or increased frequency of urination. This recurred about once daily at first, but gradually increased in frequency and amount for three months, since which time, for a period of two years, it has remained about the same, some blood appearing at the end of every micturition. Occasionally slight tenesmus and

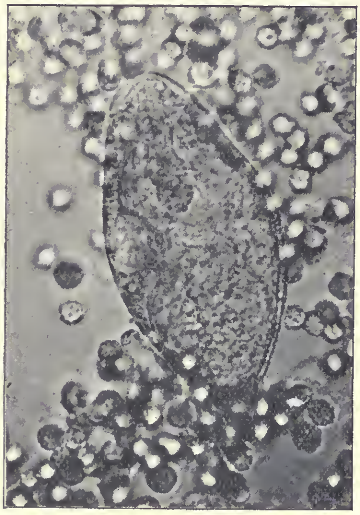
burning in the urethra has occurred. He does not recall when the urine first became turbid, but remembers that it has not been at all clear for some time, with the exception of a short period while under treatment for "cystitis and Bright's disease," at his home in Georgia.

Physical examination shows normal lungs. No enlargement of the liver, spleen, or kidneys can be found, and his general health is fairly good. A deep-seated abscess was found on the right anterior chest-wall, not mammary, as it was described. This was incised on the forenoon of March 25, 1897. Careful and repeated examinations of the pus revealed nothing pathognomonic, and this process can be considered as not connected with the *Bilharzia*. At the time of writing, this abscess is about healed. The urine voided at the time of the patient's first visit, and subsequently, was distinctly turbid at all times, sometimes tinged with blood, and contained large and small flocculi. At the end of micturition the patient passed from 1 to 10 c.cm. of blood, not coagulated. Examination of the urine revealed the following: Turbid color; amber to red; odor, not offensive; reaction, acid; specific gravity, 1016 to 1020; deposit, fairly marked, and heavy in character; urea, 0.02 to 0.024 gram in 1 c.cm., and 32 to 35 grams in twenty-four hours; albumin, present, but not more than the blood, pus, etc., would account for; sugar, none; bile, none; phosphates, considerable excess; chlorids, approximately 0.01 to 0.15 gram in 1 c.cm.

FIG. 4.



Advanced stage of development of stomach of embryo of the *distoma hematobium*. Microphotograph × 350 diam. Zeiss apochromatic, 4 mm.

Microscopic Examination.—Rather large quantities of blood, pus, and mucus, and many epithelial cells of all the layers of the bladder; also, intact aggregations of the same. Renal elements could not be found, nor were evidences of a pyelitis to be made out. The absence of a renal lesion thus indicated is corroborated by a normal daily excretion of urea as above. In addition to the above, every specimen showed a small or large number of the eggs of the *Bilharzia hematobia*, which settled the diagnosis.

These ova vary much in size, shape, and state of development, but all have a transparent shell with a terminal spine. Harley,[14] Brock,[15] Zancarol,[16] and others state that the lateral spine is only found on the eggs discharged from the bowel, and not on those found in the urine. The less developed ova show a mass of granular protoplasm, with no distinct structure on the interior of the shell, as shown in Fig. 5. The more fully developed eggs, seen in a recently voided specimen of urine, show the shell and its spine as before, containing the more distinct ovum made up of numerous round and circularly marked bodies or cells; the beginning of which may be seen in portions of Fig. 5. If this is carefully observed, even without the addition of water, in many instances, its development may be followed under the eye. There are occasional twitching movements of the mass, and then a rudimentary organ (the stomach) is seen to slowly develop at the upper end of the ovum, as seen in Fig. 1. This gradually elongates, and an advanced state is shown in Fig. 4. This is followed by the formation on each side of the above sac of two hollow spaces, which gradually develop granular contents; the beginning of this structure may be seen on one side of Fig. 4, and more complete in Fig. 6. These then elongate into two ducts, shown slightly in Fig. 2. At the same time several large round cells are developed posteriorly (Fig. 2), the so-called sarcode globules of Cobbold. Cilia then appear on the surface of the embryo. During this time the embryo executes spasmodic movements, and sooner or later the shell bursts longitudinally, whether by the efforts of the embryo, or by transudation of fluid into the shell, is not settled, and then, after escaping, the embryo moves about with furious lashing of the cilia. Fig. 3 shows the embryo with cilia, also the two

FIG. 5.

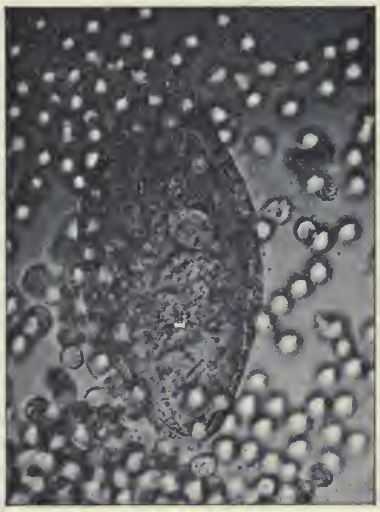
ducts before mentioned, as well as the empty shell. Soon after the liberation of the embryo it discharges the sarcode globules, also seen in Fig. 3, and continues to swim about empty for a time.

It is a most difficult task to obtain these microphotographs, as the changes the embryo undergoes are oftentimes so rapid that they have passed before the necessary manipulations for an exposure can be completed. The movements of the embryo at the time of exposure also ruin many plates.

The period of incubation of the *Bilharzia* is generally considered to be short (a few weeks). Hatch reports a case in which it was four weeks. This period for our patient has been forty-one days at the very least, counting that the infection could have occurred during his very last day on African soil.

Treatment.—Gallic acid was administered in gram doses four or five times a day, which materially diminished the amount of pus and almost stopped the hematuria. For some days methylene blue (Merck) has been given in addition. At the time of writing, the amount of pus is very much less, and for a few days there had been no blood at all, but it appeared again in very small amounts at infrequent intervals. The ova are present still in large numbers, and while they have been closely observed from day to day, I noted for the first time, on April 5th, that a small number had taken up the blue coloring matter now present in the urine. Those that do so are found to be dead; if the blue is the cause of death, or if only the dead ones take it up, I am at present unable to say. Fouquet,[17] Sonsino, and Wortabeh have written articles on the therapy of the condition.

FIG. 6.



Egg of *distoma hematobium* showing hollow spaces. Microphotograph × 350 diam. Zeiss apochromatic, 4 mm.

As to prognosis: Most of the authorities agree that many of the cases regain health with little or no treatment; in other words, barring reinfection, the condition is a self-limited disease. There are of course fatal cases where the parasite is the cause of severe cystitis, hydro- or pyonephrosis, nephritis, dysentery, severe anemia from the loss of blood, etc. Tuberculosis and carcinoma, as well as renal and vesical stones, are very common with *Bilharzia*, and in what connection they occur with the latter, whether due to a consequent irritation or to other causes is, according to quoted authorities, still an open question.

HOSPITAL REPORT.

UMBILICAL SEPSIS IN THE NEWBORN, OCCURRING AT THE NURSERY AND CHILD'S HOSPITAL, NEW YORK, DURING 1896.

BY SAMUEL W. LAMBERT, M.D.,
OF NEW YORK;
EX-VISITING PHYSICIAN TO THE HOSPITAL.

IT has been the misfortune of the obstetric department of the Nursery and Child's Hospital to lose five babies from umbilical sepsis during the past year. In addition, a number of patients have presented symptoms of a milder degree of the same infection. The following facts and deductions are derived from a study of all the babies born at the hospital during the twelve months ending December 1, 1896: There have been 169 births during this period. The history charts of three of these have been mislaid, and are therefore not available. Thirteen children, born prematurely, died of inanition a few hours after birth, and six children were stillborn. There remain 147 cases for study.

The normal process of healing of the umbilical wound is of a double nature, consisting of the mummification of the stump of the cord plus the granulation of its point of attachment, and its healing by second intention. The navel of a newborn child consists of a quite prominent circular fold of skin, which surrounds and extends upward on the gelatinous cord to which it is attached quite firmly. During the mummification of the cord, the blood-vessels and surrounding Whartonian jelly dry up and become transformed into a hard, contracted, brittle mass. The attached base is separated from the living tissue underneath by a process of granulation. After the stump has separated, the central mass of granulating tissue contracts and recedes below the general skin level of the abdomen, and at the same time the circular fold of skin contracts, and finally becomes level, or nearly so. The central ulcer cicatrizes, and the navel is healed. A fixed time limit as to when this normal process should be ended cannot be determined. It is usually completed before the end of the second week of life. During this period of fourteen days every child must accommodate itself to a number of changes in its physiology, and all abnormal symptoms cannot be attributed to any one cause. Infection of the umbilicus is not uncommon, and should be thought of in the case of every ill baby under one month of age.

The pathology of the navel of the newborn child may be included in the one word "sepsis." The question is purely one of wound infection by one or more varieties of bacteria. This wound is a granulation wound, to the surface of which certain dead tissues (the cord) are adherent. The infection may be saprophytic and limited to the cord, or truly pathogenic, the germs invading the living tissue, or both forms of infection may exist at the same time. The germs of decomposition cause local symptoms in the stump of the cord; an odor of decaying animal matter and an abnormal amount of moisture is present, and there is a delay in its separation. Serious effects have not resulted to the baby from such decomposition, but the liability to pathogenic infection is undoubtedly increased by such a process. The lesions resulting from the infection of the umbilical ulcer are the same as occur in any wound. Any of the following forms of inflammation may result: Erysipelas, cellulitis, gangrene, lymphangitis, phlebitis, or arteritis.

The symptoms of umbilical sepsis may be limited to the local evidences of inflammation, or to these may be added general symptoms of a systemic infection. The local signs vary with the form of inflammation. Excessive granulation with discharge of pus, infiltration of the surrounding skin, with or without the formation of abscesses, or more or less extensive gangrene may be present. Erysipelas or lymphangitis starting from the umbilicus will present the usual diffuse or limited redness characteristic of these lesions. The very fatal inflammations of the umbilical vein and of the hypogastric arteries give no positive local signs of their existence; they may be present with any of the forms of local inflammation just mentioned. The general symptoms of septic infection are fever, loss of weight, jaundice, skin eruptions, gastro-enteric symptoms, abscesses, thromboses of the veins or arteries.

In the series of cases under consideration fever has been observed 95 times, and granulations of the umbilicus have demanded treatment 47 times. Eighteen patients showed quite decided evidences of sepsis, and of these five died. The following will show the day the cord became detached, all the patients being included in the list, except two, who died with the cord still attached: Fourth day, 2 cases; fifth, 12; sixth, 18; seventh, 23; eighth, 16; ninth, 22; tenth, 16; eleventh, 12; twelfth, 7; thirteenth, 9; fourteenth, 4; fifteenth, 2; sixteenth, 1; and nineteenth, 1. This table, which includes all cases, septic or otherwise, shows that in 119 cases (eighty per cent.) the stump of the cord came off between the fifth and eleventh days. The granulation and final healing of the umbilical ulcer has not been the subject of such careful observation as the separation of the cord. Forty-seven cases are recorded as having moist granulations after the separation of the cord, and thirty-five of these received special treatment to assist the delayed healing of the ulcer.

The first thing which becomes evident in a study of the cases is the prevalence of fever during the months of July, August, and September. During these months forty cases were recorded. Of these forty, only four cases remained free from fever reaching 100° F., or more. This real epidemic was characterized by a peculiar skin eruption, which is described below, and was coincident with the delivery in the wards of one of the patients who became ill of a very virulent sepsis, from the effects of which she died. No effort was made to connect the two events by bacterial examinations.

The fever of sepsis runs quite an irregular course, and serves more as an indication that infection exists than as a guide to the severity of that infection. It is the pulse-rate and heart action which must lead to an appreciation of the prognosis in any case. There have been ninety-five cases of fever among the 147 cases, or sixty-five per cent. These temperatures occur either during the first four days of life or develop after the first four days, or they run through both the early and the later days of the first fortnight. There were fifty-four cases of initial temperature alone, fifteen cases of later temperature, and twenty-six cases of both forms combined. Dr. Holt distinguishes one class in connection with such initial temperatures. Those cases which begin soon after birth and which cease upon the exhibition of food are designated by him "inanition temperatures," and are due to starvation. The following facts indicate that there were several causes present to account for the temperatures met with. Fifteen of the eighteen cases which were undoubtedly septic presented an initial temperature; thirty-three of the thirty-seven cases of fever occurring during the epidemic-like outbreak were initial temperatures, and in seventeen of the thirty-three patients there was a subsequent rise in temperature. Eleven of the thirty-three became infected and two died of the disease.

The relation of a moist granulating navel wound to fever is shown by the following statistics: Of the 47 cases of granulating umbilicus, 15 patients had "initial fever," 8 had a later rise of temperature, and 10 had both forms. Only 14 remained free from a rise of temperature. An average of 8 of the 18 septic cases shows that the gastro-enteric symptoms disappeared on the twenty-first day, and the bowels became normal. The remaining 10 patients continued to have undigested mucous stools as long as they were under observation. None of these cases presented the clinical picture of pyemia, so that abscesses were conspicuous by their absence. The twenty-first day was the average one upon which 11 of the 18 septic patients regained their birth weight; the remaining 7 did not regain their birth weight at all. The total loss of weight amounted to 32, 42, 11, 24, and 18 ounces in the patients dying of sepsis on the twenty-second, twentieth, nineteenth, twelfth, and fifteenth day, *postpartum*, respectively. The milder cases of sepsis showed loss of weight, but to a much less degree, the average initial loss of the 18 septic cases being 13 ounces. The average initial loss met with in the fever cases was 11 ounces, and in the non-febrile cases 9 ounces. It must be inferred, therefore, that the initial loss of weight is a fair index of the child's general condition, and that an excessive loss is characteristic of at least one serious condition, namely, a beginning sepsis.

None of these patients suffered from the severer forms of icterus, which are apt to accompany the inflammations of the umbilical vein. The four autopsies showed that the arteries rather than the vein had been attacked by the septic process. Jaundice is a very common symptom in the newborn child, and has no diagnostic value in connection with septic infection unless it develops to an extreme degree. Of the fatal cases, not one patient died jaundiced, and only one was jaundiced during the course of its illness.

Sixty-one cases of jaundice occurred in the series of 147 cases. Of these, 7 patients presented symptoms of sepsis. These 61 cases may be arranged according to the day on which the jaundice was last noted, as follows: As late as the third day in 8 cases; fourth, 5; fifth, 14; sixth, 8; seventh, 2; eighth, 4; ninth, 3; tenth, 3; eleventh, 1; thirteenth, 1; fourteenth, 4; sixteenth, 1; eighteenth, 3; twenty-first, 1; twenty-second, 1; twenty-eighth, 1, and thirtieth, 1.

There was only one form of septic eruption met with, and it occurred in 8 children born between July 17th and September 14th. The eruption was like that of pemphigus, and consisted of bullæ varying in diameter from ¼ to 1½ inches. They contained blood-stained serum. Of these 8 patients, 2 died. This outbreak was of the nature of an epidemic, as described above. The distribution of the eruption indicated the presence of a general infection, for it was not directly connected with the umbilicus. The bullæ occurred on the neck and face in five cases, and on the trunk in three. The cases did not look like those of syphilitic pemphigus, and the eruption was not present to any extent on the extremities. Two cases of syphilitic bullous eruption occurred early in the year, and each ran its course without fever as a prominent symptom.

The fatal cases present the most typical pictures of infantile sepsis.

CASE I.—The child was delivered by forceps. It lost weight from birth until the fifth day, then gained in weight one day, and finally lost daily until it died on the twenty-second day, *postpartum*. Fever began on the second day and was continuously present, except on the sixth day. The stools were always green, and the baby vomited. The cord came off on the fourteenth day, and the umbilicus showed no evidence of inflammation, except that a band could be felt extending upward along the course of the umbilical vein. The right foot became swollen, and the heel and toes gangrenous.

Autopsy.—The umbilicus appeared normal. In the umbilical vein there was a fusiform clot three inches in length. There were also small clots in the arteries, and beneath them small collections of pus in the tissues. There was a firm clot in the thoracic aorta extending down to the bifurcation, and a clot in the right femoral artery at the middle third of the thigh, extending into the popliteal space, but not beyond. The left femoral artery was free, but a firm clot in the left femoral vein extended upward to the bifurcation of the iliacs. The right iliac vein was free, and no clot was present in the inferior vena cava. There was an extensive ulceration in the colon. Cultures from the pus in the tissues showed the presence of staphylococci.

CASE II.—This child was born after a dry labor lasting fifty-eight hours. It lost seventeen ounces in three days, and continued to lose until at the time of its death, on the twentieth day, it had lost forty-two ounces. It had a low fever until the sixth day, and from the sixth day until death occurred its daily temperature ranged between 101° and 104° F. It vomited frequently and had a green, mucous diarrhea.

Autopsy.—On opening the abdomen the umbilical vein appeared to be normal. The right hypogastric artery appeared swollen and reddish for a distance of three-quarters of an inch from the umbilicus. On manipulation, grayish-brown, grumous pus escaped from the umbilicus, and a probe was readily introduced into the artery, which collapsed with the escape of its contents. The left artery contained a firm clot. A culture of the pus from the right artery showed a pure culture of the combined staphylococcus aureus and albus. The cord was still adherent.

CASE III.—The child was born in easy labor. It had lost fourteen ounces by the fourth day, but then gained in weight slowly until the sixteenth day, but never reached its birth weight. From the sixteenth to the nineteenth day it lost in weight. The first occurrence of fever was noted on the seventeenth day, and this continued until death. The bowels were never normal, and the baby was jaundiced during the first week of its life. The cord was still adherent.

Autopsy.—There was a fusiform swelling of the right hypogastric artery just below the umbilicus, which, upon being incised, allowed the escape of bloody pus. The left artery and the vein were normal. The cord was attached to the umbilicus, and at its base there was an excoriation extending about one inch in every direction. No cultures were made.

CASE IV.—Labor was normal. The child lost twelve ounces on the fourth day, and then continued to lose steadily until the twelfth day, when it died. Its temperature rose suddenly to a high point on the second day, and continued most of the time above 102° F., until death occurred. The bowels were never normal. There was no vomiting. A pemphigus-like skin eruption appeared on the fourth day upon the neck, and spread rapidly over the shoulders. The cord came off on the sixth day.

Autopsy.—On opening the umbilicus it was found to contain a discolored, yellow, liquid mass, which seemed to extend through into the artery and vein.

CASE V.—This child was born two days after the one whose history has just been given. It lost 12 ounces in weight on the third day, and 18 ounces on the fifteenth, when it died. From the third until the twelfth day it gained, but never reached its birth weight. There was an initial temperature of three-days' duration, reaching 101.2° F. From the fourth to the twelfth day there was no rise of temperature, but during the last three days the temperature ranged between 99° and 102° F. The bowels were never normal. The cord came off on the tenth day, and the umbilicus contained pus, but there was no tenderness about it. An eruption on the child's neck and abdomen, similar to that met with in the last case, began on the fifth day, but was not very extensive. No autopsy was allowed.

The plan of treatment in vogue at the Nursery and Child's Hospital is as follows: After pulsation in the cord has ceased, it is stripped of Wharton's jelly toward the placenta, and then ligated, usually about an inch and a half or two inches from the navel, another ligature being placed on the placental side. The cord is cut with dull scissors close to the first ligature. The remaining portion of Wharton's jelly is squeezed out, the cut end of the cord is thoroughly sponged with a solution of mercuric chlorid, and then thoroughly mopped and dried with sterile absorbent cotton. Some kind of powder is dusted over the stump and its base, and the dressing is completed by a wrapping of sterile cotton or gauze, which is tied on with sterile tape. The original cotton or gauze dressing is not disturbed or removed unless it becomes wet. The base is dusted only with some drying powder twice daily until the cord falls off. The baby is gently sponged twice daily with warm water, and wiped perfectly dry; it does not receive a hot bath until the cord has become detached and the umbilicus has healed.

The question of prophylaxis against infection of the navel is considered under two heads: First, the adoption of means to hasten the drying of the stump of the cord; second, the prevention of the access of bacteria to the umbilical ulcer. The accepted views of to-day concerning the bacterial causes of inflammation have led the writers of all recent text-books which treat of the subject to insist upon the importance of the last-named measure, but at the same time they have lost sight of the equally important matter of hastening the drying of the dead tissue of the cord. The routine treatment of the cord advised by these authorities consists in the application of an aseptic occlusive dressing of absorbent cotton, either sterilized or medicated with boric acid, to which is added some form of antiseptic powder.[1]

The old method of dressing the cord is well described by Dr. C. D. Meigs in his "Obstetrics," published in 1856. The dressing consists of a piece of linen four by eight inches in size, which is folded to a square. A slit is cut in the center of the double square, and then, to *quote verbatim*, "Through this slit let the remnant of the navel string be passed so as to let the double disk of linen lie upon the belly of the infant. The cord should be laid down flat upon the disk pointing upward toward the scrobich, and the linen should next be turned up so as to cover it. The right side should be turned over the cord to the left," and *vice versa*, etc. This passage is quoted in full, because of its bearing on certain conclusions which have been drawn from experiments detailed below.

Dr. M. Cohn[1] of Berlin has recently published an article on septic infection of the navel, in which he details certain experiments made to determine the conditions which influence mummification of the cord. The following experiments are, in part, a repetition of those made by him, having the same object in view: The cords of seven placentæ were taken and cut into pieces about two inches in length. A ligature was tied about the ends of each piece, which were thus made to resemble as nearly as possible the portion of the cord left attached to the umbilicus. One piece was treated in the same manner as was the stump on the child, while other pieces were given various kinds of treatment, and the condition of the separate pieces was noted daily. These pieces, wrapped in their experimental dressings, were rolled up in a flannel binder, such as is used on a baby's abdomen, and placed upon a shelf in the hospital laboratory. This room has gas burning in it during every hour of the day and night, and is always dry and warm, so that the conditions are conducive to the desiccation of any dead tissues left in it. The results obtained by treating these pieces of cord were as follows: Pieces of four cords were powdered with boric acid, bismuth subnitrate, talcum, or starch, and wrapped in absorbent cotton and flannel in the manner described. It made very little difference which form of "drying powder" was used. If anything, the talcum seemed to act quickest. Pieces of two of these cords were dressed with cotton alone, without any powder whatever, and both dried up more quickly than any of the pieces to which the powder had been applied. Pieces of three of the same cords were hung up exposed to the air; two of them in a hot, dry room became dry and brittle in twenty-four hours; the third, a piece of the thickest cord, was hung in a cold room by an open window; it also was perfectly dry in twenty-four hours, but did not become brittle until the second day. The inference is very plain, and coincides with that drawn by Cohn from the similar experiments conducted by him. *It is the access to the air which furthers the mummification of the stump of the cord, and all ordinary drying powders and all occlusive dressings are a hindrance to that process.*

In order to discover the effect of shutting off the access of air entirely, a piece of cord was hung free in a stoppered bottle. On the third day it was in a moist condition of stinking decomposition. Even such a piece of foul-smelling cord will become dry and brittle when exposed to the air for twenty-four hours. The stearate of zinc is a comparatively new drug which has been recommended for local applications; it is claimed that it permits free access of air to the wound. Pieces of these cords treated with it and wrapped in cotton became dry and brittle more rapidly than did any of the pieces mentioned above. Calcium chlorid is a powder that possesses marked hydroscopic powers. Pieces of cord treated with it became dry in twenty-four hours, and the surrounding absorbent cotton was so moist that several drops of fluid could be squeezed from it. A piece of cord hung in a bottle containing a considerable amount of chlorid of calcium was dry in twenty-four hours. Schep[1] of Berlin has recommended the use of a two-per-cent. solution of nitrate of silver on the cord twice daily. The pieces of the cord treated in this way did not show more rapid dessication than pieces of the same cord treated in other ways. Nitrate of silver failed to prevent the decomposition of a piece of cord hung in a bottle. A comparison between the occlusive properties of absorbent cotton and those of absorbent gauze resulted in favor of gauze as a dressing for the cord, thus demonstrating the advantages of the older method advocated by Dr. Meigs over that described by later writers.

---

[1] As examples of these authorities, compare "Précis d'Obstétrique," by Lepage & Ribemont-Dessaignes; "Lehrbuch der Geburtshilfe," by A. Martin, and the "American Text-book of Obstetrics."

[1] *Therapeutische Monatshefte*, 1896, x, 3, 4.

These various experiments were repeated in the umbilical dressings of living infants. The results in eight cases were as follows: Stearate of zinc was used four times with satisfactory results. The cords dried up even more rapidly than the pieces of the same cords treated with the same agent in the laboratory. One cord was treated with a two-per-cent. solution of nitrate of silver twice a day. It dried up very quickly, and was brittle on the second day. The cord of another baby was left exposed to the air, through a hole in the clothing, without dressing of any kind; it was dry and brittle in twenty-four hours, as were the pieces hung up in the laboratory. Two cords were treated with powdered calcium chlorid. They dried up within twenty-four hours, but the liquefied drug soaked through the clothing of the child, and proved irritating to the skin of the abdomen, though no harm resulted from its use. Although both cords were completely dry on the first day *post-partum*, they only separated on the fourth and eighth days, respectively.

The second point in the prophylactic treatment of the umbilical wound is the prevention of the access of bacteria to it. No one can deny the necessity for this, but the means adopted should not hinder the drying process in the cord. The point of danger is the attached base of the cord, and the period of danger ends, not with the separation of the cord, but with the cicatrizing of the granulating surface beneath it.

In conclusion, it may be said that a proper umbilical dressing consists of a gauze or linen covering for the stump, applied without "drying powder." The base of the cord should be surrounded by an occlusive dressing, but the cord itself should be exposed frequently to the air. The care of the baby during its first ten days of life is important. A daily full bath should usually be omitted until after the navel is healed, and the umbilicus should be protected from all moisture, especially from the urine of the child. If the dressing on the cord becomes wet, it should be changed at once. Of all the powders experimented with, the stearate of zinc seems to be the best. Calcium chlorid is a great absorber of water, but its solutions are too irritating to allow of its being recommended for general use.

When a septic process has once begun its treatment is very unsatisfactory. All abscesses should be opened and the gastro-enteric symptoms controlled as much as possible by change of food and lavage of the stomach and intestinal tract. Drugs are of little or no value, and food and stimulants make up the whole pharmacopeia for new-born babies.

I wish to express my thanks to Drs. Edgerton, Neumann, and La Fetra of the house staff for their efficient aid in searching the hospital records, and for assistance in making the various experiments.

MEDICAL PROGRESS.

Disinfection of Soiled Linen.—BEYER (*Fortschrit. de Médicine*, No. 1, 1897) has tested different methods employed for the disinfection of bed linen and underclothing. The ordinary methods by boiling are not suited to these articles, as the presence of blood, pus, and feces causes an ineradicable stain if a high temperature is used. Soaking the garments in solutions of various soaps for one or two days failed in every instance to kill cholera, typhoid, and pyogenic organisms which were mixed with the feces with which the garments were smeared. In some cases the germs were killed when the solutions containing the linen were kept at 50° C. for a few hours. With lime-water the results were much better. Sample garments which were soaked in this solution for twenty-four hours were found to be sterilized. An equally good result was obtained in a hospital where about one-half a cubic meter of soiled linen was soaked in lime-water for forty-eight hours—or for twenty-four hours if the clothing was first rinsed with lime-water and then placed in a fresh solution. The lime-water does not injure linen or cotton goods, but shrinks woolen to such an extent as to prevent its use.

Laminectomy for Simple Fracture.—Mortality following this operation has been variously estimated at from thirty to fifty per cent. GALLAUDET, in the *Annals of Surgery*, January, 1897, says that these percentages are misleading, because the cases are not classified as regards the seat of the injury. The prognosis, if the injury is in the lumbar region, is very favorable. It grows less so the higher the injury. He reports three cases operated upon by himself, two in the lumbar region and one in the upper dorsal. The lumbar cases recovered from operation, and are living in an improved condition. The dorsal case died of shock six hours after the operation. The writer urges an immediate laminectomy in all cases of fracture of the lumbar laminæ, in which the diagnosis is reasonably clear.

The Presence of Nerves in New Growths.—YOUNG (*Journal of Experimental Medicine*, Vol. II., p. 1) has examined a number of malignant and benign tumors, in order to determine the presence therein of nerve fibers.

---

[1] *Therapeutische Monatshefte*, 1895, ix, 6.

In five of ten cases of carcinoma and sarcoma and myxoma, the presence of nerves was positively demonstrated. In sarcoma, at least, the nerves seem to be as much an integral portion of the tumor substance as the sarcomatous blood-vessels. Their origin in carcinoma was not so clear, and it is possible that those seen were nerves of normal structures which were surrounded by the invading cancer tissue. This is an entirely new subject, and as yet no explanation has been given of the function of nerves in new growths, except the suggestion that they may be vasomotor in character.

Experiments upon Metabolism Made by the U. S. Department of Agriculture.—Experiments upon metabolism have frequently been made in Europe, but the first careful investigation of this sort to be carried out in the United States, according to a writer in *Science*, March 26, 1897, has recently been undertaken at Wesleyan University in Connecticut under the auspices of the Department of Agriculture. The apparatus included a so-called respiration chamber 7 x 4 x 6.5 feet, with glass doors, and containing a chair, table, and cot bed. A man can remain in this chamber for an indefinite time without inconvenience. A current of fresh air passes through the box. All food, drink, excretory products, and the currents of air are weighed or measured and chemically analyzed. The duration of the experiments varied from two and a half to twelve days. Certain days were passed in absolute rest, others in hard study, and still others in hard muscular work. Results showed that during the periods of rest the subject gained about half an ounce of protein and lost half an ounce of fat a day. With severe mental work the results were almost exactly the same. During the period of hard muscular work the food which had proved sufficient for the periods of rest and of brain work did not suffice for the needs of the body, and the subject lost daily a sixth of an ounce of protein and seven ounces of fat. The investigations will be continued, and attempts will be made to discover the kinds of food best suited to different kinds of work.

THERAPEUTIC NOTES.

Glycero-phosphates in Neurasthenia.—In the *Bulletin Générale de Thérapeutique*, February 8, 1897, BARDET denies that the glycero-phosphates have any specific action in neurasthenia. He attributes the good results which follow their ingestion to the ease with which they are disintegrated and furnish phosphorus in a ready assimilative form. In certain cases of neuralgia success has followed their use by hypodermic injection, a mode of action which is not well understood.

Glycero-phosphates probably represent the form in which phosphorus exists, not only in the nervous system but also in the nutrient fluids from which the bones draw their phosphates. It is probable, also, that the iron in a blood-corpuscle exists in the form of a glycero-phosphate. The indication for their use exists not only in neurasthenia, but also in diabetes, anemia, scrofula, and rickets. ROBIN recommends the use of a mixture of the glycero-phosphate of lime 5, soda 1.5, potassium 1.5, magnesium 1.5, and iron .75 grams twice a day.

For Nervous Hyperacidity of the Stomach:

℞	Strontium bromid (pure), . . .	ʒ iii
	Aq. menth. pip., ...	ʒ xv

Sig. Teaspoonful twice daily in milk at mealtime.

—EINHORN.

For an Acutely Inflamed Rectum:

℞	Chloral hydrate, . . .	grs. xlv to lxxv
	Tannic acid, ...	grs. xxiv
	Lime water, ...	Oi

Sig. One-fourth to one-third of this quantity is to be mixed with ℥ xii of warm water or thin starch water, and 5 or 6 ounces injected into the rectum at a time and retained as long as possible.—EWALD.

The Treatment of Nephritis with Antipyrin.—MODINOS (*Gaz. degli ospedali*, December 20, 1896) says it is not yet determined whether the various forms of nephritis are distinct diseases or variations of the same disease. Though the causes are various, the general conclusion that all cases of true nephritis are due to bacterial infection seems warranted. The multiplicity of remedies employed furnishes the most palpable evidence of the uncertainty that obtains as regards the etiology of the disease. Not one of them—tannin, sodium tannate, gallic acid, salts of lead, potassium iodid, salts of strontium, fuchsin, methylin blue, tincture of cantharides, etc.—has gained the general verdict of possessing any preeminent degree of efficaciousness. In the treatment of the various forms of nephritis we must endeavor above everything to stimulate the action of the kidneys, and, furthermore, to check the development of toxic products, and to neutralize the toxins already evolved.

For accomplishing the first two ends, a milk diet is best suited; for the neutralization of the toxic products contained in the urine, the author recommends antipyrin as the suitable remedy. After many experiments with this drug, he has found it useful in most varieties of nephritis, whether acute or subacute, primary or secondary, and also in nephritis of the postmalarial type. He gives from 12 to 20 grains daily in divided doses. Under this treatment the quantity of albumin in the urine was found to diminish, and, in a remarkably short time, to disappear altogether, together with the symptoms of renal intoxication.

Soluble Phosphate of Bismuth.—According to DÖRFLER, LEISER, and SÖHLE (*Gas. Heb. de Méd. et de Chir.*, March 18, 1887) this salt contains twenty per cent. of phosphate of soda. It is very soluble in water, and if injected under the skin of animals it does not produce any injurious or toxic effect. It has a marked astringent and antiseptic action in the intestinal canal. It is recommended in diarrhea of children, in gastralgia, tuberculosis of the small intestine, typhoid fever, and cholera morbus, and in this last infection particularly, it allays vomiting, reduces the number of stools, and favors recovery. The dose is .2 to .5 grams (3 to 8 grains) three times a day.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

THE DIAGNOSIS AND TREATMENT OF CHOLELITHIASIS.

THIS subject was most admirably discussed at a recent meeting of the New York Academy of Medicine. The five papers which were presented—each one by a person competent to speak with authority upon the particular phase of the subject allotted to him—constituted a most complete and instructive symposium. All of these papers have been presented in the columns of our last two numbers, and the readers of the NEWS are to be congratulated on the opportunity thus afforded them of enjoying this condensed and interesting discussion.

Among the salient points presented was the fact that the diagnosis of gall-stones is frequently obscure and too often overlooked in ascribing the symptoms to other causes. In confirmation of this, many interesting cases were cited by Dr. Peabody, and later by Dr. Draper. In the "Chemistry of Gall-stones," so interestingly presented by Professor Chittenden, while no new facts were developed, the insolubility of the stones *in situ* was demonstrated, as was the absolute futility of any therapeutic efforts directed to that end. Agents that tended to increase the flow and alkalinity of the bile and arouse and maintain peristaltic action of the ducts were physiologically indicated. Dr. Thompson held that this could be most satisfactorily accomplished by a carefully regulated diet, appropriate doses of sodium phosphate, and horseback riding. It will thus be seen that the drift of the argument was in favor of preventive measures, all admitting the hopelessness of treatment other than surgical after gall-stones had once formed. How surgical procedures could be rendered safe and effectual in surgery of the gall-bladder and the common duct was presented and enriched from the clinical experience of those masters of surgical art, Gerster and Lange.

In the general discussion which followed, the whole subject was summed up in a masterful way by Dr. Charles McBurney. Regarding the prevention of gall-stones he thought none would suffer who form proper habits of exercise and maintain healthy elimination during the comparatively short period of gall-stone formation. The cases could be divided into two classes: those which should be operated upon and those which should not be operated upon. As a rule we must consider as inoperable those cases in which there are frequent and short attacks, with sudden relief, indicating the passage of small gall-stones, thus demonstrating the probability of obtaining relief in a similar way again. For, as a rule, when a person passed small stones he did not have large ones. On the other hand, when an operation was indicated it should be done promptly before the formation of ulcerated adhesions, or the development of cholemia. As had been pointed out by Dr. Lange, the operative dangers related to cholemia and the tendency to hemorrhage depended thereon. It was to the prevention of these conditions, or the anticipation of them by early operation, that attention should be directed if progress is to be made in the treatment of cholelithiasis. Let the medical practitioner mark well those cases which do not pass their gall-stones as the ones which should be subjected to operation at an early stage.

THE ADDED POWER OF THE STATE BOARD OF CHARITIES IN RELATION TO MEDICAL DISPENSARIES.

A DECIDED step in advance has been taken by the advocates of reform in the matter of indiscriminate dispensing of medical charity in this State in the bill that has recently passed both houses of the Legislature, and which now but awaits the signature of the Governor to become a law. This bill provides that all dispensaries, whether of a municipal or private character, shall be subject to the supervision and control of the State Board of Charities, and this body is empowered to "annul the corporation, or suspend the operations, or to revoke the license of any dispensary for wilful neglect or failure on the part of its managers, trustees, officers, or employees to comply with the rules and regulations so established."

Chapter 771 of the Laws of 1895 defined the duties and privileges of the State Charity Commissioners, but power was not given them to close any dispensary which, in their opinion, was not fulfilling the object for which it was founded. For many years an earnest effort has been made toward obtaining the authority embodied in the terms of the present bill, and now that this is all but achieved, it remains to be seen how it will be enforced.

On page 82 of the annual report of the State Board of Charities for the year 1896, which was presented to the Legislature February 25, 1897, in the section devoted to the investigation of the dispensary system, is the following: "During the last twenty-five years these institutions have rapidly increased and the competition has been so great that the question has been raised as to the real value of this method of administering relief. . . . To fulfill its proper mission it [the dispensary] should be so organized and managed that only the really sick poor should be able to secure its benefits. It has been found that managers of dispensaries rarely institute any adequate inquiry into the means or ability of patients to pay for the medical services of the physician or for the medicines which they receive. . . . It is very evident that when any so-called charities have so far departed from their original objects and purposes as to invite, or even allow, persons of wealth or moderate competence to enjoy their benefits, they have ceased to fulfill their proper functions and should be suppressed."

If the present bill becomes a law, it will go into effect on the first day of October, 1897, and as it is an open secret that the governing board of more than one long-established and powerful dispensary in this city is opposed to change in any form of the methods now in force, it is reasonable to assume that influence will be brought to bear in order to modify or abrogate such rules or regulations as may be promulgated by the Commissioners as to make them practically useless. If this should prove to be the case, and there are many who will eagerly watch the progress of the Commissioners along the rugged road of reform, it may be said without fear of contradiction that the several representative medical societies of the State, and especially the Medical Society of the County of New York and the County Medical Association, will be prepared to exert their influence and invoke such legislative action as will serve to amend and strengthen the law and thus assure to physicians and laymen alike the economic benefits that have been so long withheld.

THE ACTUAL DANGER OF AIR EMBOLISM.

For many years, text-books on surgery and surgeons in active practice have taught that the entrance of air into the veins was a most serious accident, followed in a large proportion of instances by death. Some ten years ago the writer, when engaged in making a large number of experiments in which remedies were injected directly into the jugular vein of animals, particularly dogs, noticed that in no instance was the simultaneous entrance of air followed by any particular effects. This led him to undertake researches directed to the elucidation of the question now under discussion. The results of these experiments demonstrated that very large quantities of air could be injected into the vein of a living animal without deleterious influence. Thus 20 c.cm. of air injected into the left jugular vein of a dog weighing forty pounds, produced absolutely no effect whatever save that the respiration was slightly quickened for one minute after the injection, the animal, as soon as it was set free, running about the room as happily as ever. Blood-pressure tracings taken from other animals receiving large quantities of air into their veins showed that its injection influenced very slightly, if at all, the blood pressure and pulse-rate.

A paper, detailing these experiments and giving some of the tracings, was published in the *Therapeutic Gazette* for September, 1889, and studies were also made of the effects produced by injecting air into an artery. Such an injection was always followed by the most serious results, which, according to the teachings of the late Professor Gross, were to be expected. Ordinarily, however, the blood pressure in the artery is so high that it is impossible for air to enter, except it be deliberately injected, so that, aside from deliberate experiment, the probability of air entering an artery is very remote. In the paper to which I have referred, quite a number of bibliographical references are given, and instances quoted in which the entrance of air into a vein resulted in the death of the animal or the man who received it, but it is a noteworthy fact that the great majority of these researches were made in the early part of the present century and some of them were exceedingly crude. It seems to be an undoubted fact that the entrance of very extraordinary amounts of air is capable of producing death in man and animals, and this we can readily understand, for if the cardiac cavities are entirely filled with air to the almost total exclusion of blood, large quantities of air would be driven into the arteries supplying the vital centers at the base of the brain and produce results identical with those following the injection of air directly into the carotid artery.

On the other hand, it would seem probable that air embolism is only fatal when a small globule of air entering a vein happens to plug an artery supplying a very vital point. Recently, the writer has inadvertently injected a very large globule of air into the median basilic vein of the arm in two men of advanced years, without producing death. Both cases were suffering from toxemia, requiring intravenous saline injections. In both instances there was after the injection a severe rigor, in one case immediately after the air entered the vein, in the other an hour afterward; but this symptom invariably follows the injection of saline solutions when no air is injected.

One of the most exhaustive papers which has been written upon this subject is that by Amussat, who believed that the entrance of air into the vein was an exceedingly fatal accident, but his essay was violently attacked and partly disproved by Velpeau, Gerdy, Blandin, and Mallé, who asserted that the symptoms which Amussat detailed were due to extraneous causes and not to an air embolism. By far the most exhaustive research, however, which has been published, certainly the most exhaustive in this country, is that by Dr. Nicholas Senn, whose investigations also prove that air embolism is not as universally fatal as is commonly believed. It is interesting to note that the writer of this editorial during the reading of a paper before the Philadelphia County Medical Society upon this topic some eight or nine years ago, injected no less than 40 c.cm. of pure air directly into the jugular vein of two very small dogs without giving them any inconvenience whatever, the dogs running playfully about the room immediately afterward.

The conclusions to be drawn from the researches to which I have referred, are that very large quantities of air must enter a vein to cause death, and that no such quantity is likely to find its way into a vein which has been injured by the knife of the surgeon. It would seem probable, too, that different animals and perhaps different men, have a varying resistance to the effects of air embolism. Monkeys seem to be quite susceptible to it, as are also rabbits, while horses and dogs, according to the results so far published, seem to be comparatively invulnerable. Thus we find that Cormac blew the contents of his chest twice filled into the jugular vein of a horse, before the animal exhibited any signs of uneasiness. Barthollemy has also found that in horses, as much as six litres of air must be introduced intravenously to cause death, and from this fact assumes that a man weighing 136 pounds would have to receive over one and a half pints of air into his vein before a lethal result would be produced.

An examination of the cases which are on record in which the entrance of air into the veins is said to have produced death, reveals the fact that the conclusions in few, if any, of them will stand analysis. Other causes for the sudden demise of the patient have been possibly present, and it is interesting to note how very few cases of this character have been reported since modern methods of observation have been instituted.

The instances in which death has been said to follow the entrance of air into the uterine sinuses are much more frequent, and the *post-mortem* results on record seem to be far more reliable, but even in these cases the occurrence of sudden death and the finding of gas in the uterine sinuses and veins does not by any means prove that the death was due to the entrance of air, for statistics are continually accumulating which tend to show that the finding of air or gas in the venous system or tissues, particularly the tissues of the genito-urinary apparatus, is far more frequently due to the development of the gas by the *bacillus ærogene capsulatus*, so well described by

Welch, than to the direct entrance of ordinary atmospheric air.

If it is possible, as is claimed by some, that small air emboli entering a vein produce instant death, the question arises: How is this death produced? It seems hardly creditable that the globule of air can effectually plug a blood-vessel, since it would naturally adjust itself to the diameter of it and become more and more attentuated as it passes through capillaries of smaller and smaller dimensions.

When it comes to an explanation of the fact that arterial injection of air is followed by death, whereas a venous injection is not, I confess that I am unable to advance even a satisfactory hypothesis, unless it be that the air entering the right side of the heart from the vein is most of it sent through the pulmonary blood-vessels and expired with the rest of the gas therein contained, and that it is only when so large a quantity of air is injected that some of it passes over to the right side of the heart and arterial emboli form that death results.

Some have believed that air embolism results in the development of secondary clot emboli which produce the accidents arising from arterial injections. The other theory that air acts as a poison to the brain and vital centers is scarcely tenable. Whatever results may be obtained in the future in the study of this interesting subject, one thing seems evident, namely, that air embolism is by no means as fatal as has been generally taught, and that while it is to be avoided by every possible precaution, its occurrence is not equivalent to signing the death warrant of the patient.

In conclusion, it is of interest to draw attention to the experiments recently made by McClintock of Detroit, who proved that the injection of so large a quantity as 600 c.cm. of air into the jugular vein of a horse failed to produce death and that fifteen minutes later the enormous quantity of 1200 c.cm. of air was injected without producing fatal results, although there were for a time marked disturbances of respiration. He also found that 1 c.cm. injected into the vein of a rooster produced some dyspnea followed by complete recovery; that a rabbit receiving 20 c.cm. of air into the vein died in a little less than four minutes, but that a guinea-pig, which received more than a cubic centimeter of air, recovered entirely.

These experiments made by McClintock were designed to controvert the assertion of Drs. Seibert and Schwyzer who claimed, about six months ago, that the sudden deaths which had occurred after the injection of diphtheria antitoxin were due to air embolism. Their experiments were made upon guinea-pigs, and the amount of air injected was so enormous in proportion to the size of the guinea-pig as to be far beyond the quantity which could possibly gain access to the body during the injection of diphtheria antitoxin. Thus a guinea-pig, which ordinarily weighs certainly not more than 500 grams, had injected into its jugular veins from 2 to 4 c.cm. of air, a quantity quite sufficient to entirely fill its cardiac cavities. In other words, the quantity of air which they injected into guinea-pigs would be equivalent to about 4 to 6 ounces of air into the vein of a child weighing fifty pounds.

Doubtless in the near future other studies will be made which will throw more light upon this interesting and practical subject, but the writer confesses that having seen air embolism take place in men and in animals without the serious effects usually supposed to occur under such circumstances, he has come to believe that the accident when it occurs is a far less grave event than has been commonly supposed.

H. A. HARE, M.D.

ECHOES AND NEWS.

The International Hygienic Congress.—The meeting of this association, which was advertised to occur at Madrid, Spain, in September next, has been postponed to April, 1898.

The Stuttering Habit in Germany.—An item is going the rounds of the daily press which affirms that there are more than one hundred thousand children in the national schools of Germany who stutter.

Defeat of the Optometry Bill in New York.—The so-called optometry bill granting opticians the right to refract eyes and fit glasses, which has been before the Legislature, was defeated by a vote of seventy-three to fifty-one.

Poisoned by Wild Parsnips.—William Hughes and wife and two sons, an entire family, living near Mifflin, Ind., ate freely of wild parsnips, which were mistaken for sweet anise. The father and one son lived four hours, and the mother and other son died in forty-eight hours. All suffered great agony.

Hospital Stewards to Organize.—An organization to be known as the Military and Naval Apothecaries of the State

Service has been started by the hospital stewards attached to the various regiments of militia in New York and Brooklyn. Members of the Hospital Corps of the regular army and navy have been invited to join.

Dr. Landon Carter Gray.—The many friends of Dr. Gray will be pleased to know that he has completely recovered from the severe attack of grip from which he has been suffering, and expects to attend the meeting of the Medical Congress in Washington and discharge his duties as chairman of the Executive Committee.

The Bubonic Plague Subsiding.—The total number of cases of bubonic plague in Bombay up to April 22d was 11,706, and there have been 10,020 deaths from this cause. Many of the inhabitants of Bombay are now returning to the city. The serum treatment of the disease has not met with the success that was expected.

The Chemistry and Pathology of Gout.—Dr. Luff, in his Goulstonian Lectures, delivered recently before the Royal College of Physicians in London, endeavored to establish the important deduction that the opposed qualities of meat and vegetable diets in respect to the induction of gout are due not to their proteid constituents as formerly believed, but to their inorganic salts.

Sir Andrew Clark's Biography.—A life of Sir Andrew Clark is to be added to the biographies of the year. Medical attendant to so many noted men, distinguished writers among them, it was thought that he must have left many interesting reminiscences. But it appears that he kept no journal, and that most of his notes on men and opinions are to be found on the margins of the books he read.

A Negro Woman as an M.D.—The Louisiana State Board of Medical Examiners has given a diploma to practise medicine to Mrs. Emma Wakefield, a negro woman. She is said to be the first woman of her race in the South, or, indeed, in the Union, to receive this honor. She is a daughter of ex-Senator Wakefield, and a graduate of the medical department of the New Orleans Colored University.

Increased Requirements in Medical Schools.—The Northwestern University Medical School of Chicago, otherwise known as the Chicago Medical College, has increased its requirements for admission to a standard equivalent to the requirements of the best literary colleges. Every applicant for admission must either present a diploma from some acceptable school or college, or sustain the examination.

A Chair of Vertebrate Paleontology.—The will of Edward Drinker Cope, professor of zoology and comparative anatomy in the University of Pennsylvania, has been admitted to probate in Philadelphia. He bequeaths the bulk of his estate, estimated at $100,000, to the University of Pennsylvania, and provides for the establishment of a chair of vertebrate paleontology in the Philadelphia Academy of Natural Sciences.

New York School Inspectors.—The weekly reports of these officers emphasize constantly the importance of their work. The last report shows that there were 3918 children examined. The total number excluded was 258. There were 7 cases of measles, 5 diphtheria, 1 scarlet fever, 1 croup, 2 whooping cough, 12 mumps, 31 contagious eye diseases, 169 parasitic diseases of the head, 9 of the body, 11 chickenpox, and 10 skin diseases found.

Trouble Among the Apothecaries of Chicago.—It is reported that a Chicago druggist has been condemned by a jury to to pay $1500 damages for the mistake of a prescription clerk, who used carbolic acid in a lotion for inflamed eyelids, and destroyed the sight of one of the eyes of a little child. Another druggist of the same city fares worse, a verdict for $8000 being given against him, because one of his clerks sold corrosive sublimate for calomel.

Report of the New York State Lunacy Commission.—The annual report of the State Lunacy Commission for the year ending September 30, 1896, recently presented to the Legislature, gives the whole number of registered insane on that date as 20,869, a net increase of 653 over the preceding year. The total amount expended for maintenance was $3,052,952.87; and the expenditure for new buildings, repairs, and improvements was $829,466.43.

Fire at the Woman's Medical College of New York.—The college portion of the buildings of the New York Infirmary for Women and Children, East Fifteenth street and Livingston Place, was destroyed by fire April 22d. The Woman's Medical College thus ruined was the only regular school of medicine for women in this State, and it had over one hundred students. The infirmary was founded in 1854 by Drs. Elizabeth and Emily Blackwell. The ruined building was erected by private gifts at a cost of $125,000.

The Bacterium of Mumps.—It is reported from Berlin by the correspondent of the *British Medical Journal*, that Professor Von Leyden has discovered a new diplococcus in the parotid gland secretions of persons suffering from mumps, which he takes to be the "mumps bacterium." It is distinct in appearance, and can be cultivated on the usual media. Attemps to inoculate animals proved unsuccessful. The diplococcus has been found, not only in the parotid gland secretion, but also in the pus of the inflamed gland.

The Queen's Jubilee in Edinburgh.—The citizens of Edinburgh, Scotland, are considering how to commemorate Her Majesty's long reign. Three suggestions have been made: (1) The building of a consumption hospital; (2) an extension of the Queen's Jubilee Nurses' Institute; and (3) the building of a pavilion to the Royal Infirmary for the Diseases of Women. The first-named scheme is the most needed and decidedly the most popular, 509 persons having died from phthisis pulmonalis during the year, and 320 from all other infectious diseases.

A Case of Yellow Fever at New York Quarantine.—Otis E. Bullock of Haverhill, Mass., twenty-one years old, a passenger on the steamship "Finance," which arrived April 22d from Colon, was removed, on the vessel's arrival at quarantine, to Swinburne Island, suffering from yellow fever of a most malignant type. He died soon afterward. He had been sick for several days, and had been attended by the ship's physician, but grew steadily worse. He had been a student of natural history for several years, and a few months ago joined the Frank Blake Webster company's expedition of naturalists to South America, and was on his way home.

The Semi-Centennial Meeting of the American Medical Association.—The semi-centennial meeting of the American Medical Association, which will be held in Philadelphia on the 1st, 2d, 3d, and 4th of June, 1897, bids fair to surpass in the character of the entertainment, the scientific papers, and the number in attendance any meeting which has heretofore been held. The committee in charge have been able to obtain large and roomy places of meeting for the general meetings and the section meetings all within a single block and within very short-walking distance, or immediately adjacent to the largest and most comfortable of the Philadelphia hotels. For the week preceding and following the meeting the Committee of Arrangements have also arranged for clinical courses, which will be open without charge to all physicians who may visit the city at that time.

Reduction in Steamship and Railway Rates to Moscow.—Reduction of fares for those who intend to visit the Twelfth International Medical Congress will be as follows: On French, Spanish, Norwegian, and Oriental railroads fifty per cent. On Italian railroads thirty to fifty per cent., according to distances. On Norwegian railroads a second-class ticket is valid for the first-class; a third-class ticket for the second. On the steamers of the Compagnie Générale Transatlantique, from New York to Havre, "the minimum summer rates" are charged; on its Mediterranean line fifty per cent., and on the West Indian thirty per cent. are deducted. The "Messageries Maritimes" allow thirty per cent.; the Italian line of the Mediterranean, thirty per cent.; the Constantinople-Odessa line, fifty per cent.; the Austrian Lloyd, twenty-five per cent.

A Successful Surgical Operation upon the Heart.—It is reported from Berlin that Dr. Rehe of Franfort presented a patient before the Surgical Congress, recently held in Berlin, upon whom he had operated for a lacerated wound of the heart, the first case of the kind in the history of surgery. In reporting the case, Dr. Rehe said that the man had been stabbed in the heart. In the ordinary course his death would have been certain in a very short time. He was, however, hurriedly conveyed to the hospital, where Dr. Rehe was in attendance. The doctor had him at once taken to the operating-room, where he laid bare the heart and found that there was a wound on the right side of the organ. He sewed up the wound and applied general treatment for arresting the hemorrhage. The heart worked violently during the operation, but despite the commotion of the organ the patient made good progress and soon recovered.

Obituary.—Dr. Le Roy McLean died at his home in Troy, New York, April 23d. Dr. McLean was born at Jackson, Washington county, February 12, 1831. He was of sturdy Scotch descent. He commenced the study of medicine in 1851, and graduated from the Albany Medical College with the class of 1855. He was the first in his immediate section to perform the operation of ovariotomy, in which branch he gained a high reputation, and the first in this country to open the esophagus in order to remove foreign bodies. The latter fact was noted throughout the surgical world. He performed the first successful hip-joint amputation in the war of the rebellion. Dr. McLean was a member of the American Medical Association, New York State Medical Society, the American Surgical Society, Rensselaer County Medical Society, honorary member of the New York State Association of Railway Surgeons.—Dr. Frank Abbott, Dean of the New York College of Dentistry, and a well-known physician, died suddenly April 20th, of heart disease, at his residence in New York. Dr. Abbott was born at Shapleigh, Me., September 5, 1836. His ancestors came to America in 1640, and settled in Andover, Mass. After taking his degree he removed to Johnstown, N. Y., and practised dentistry continuously there, except for the time spent in the army during the late war, until 1863. A year later Dr. Abbott removed to New York City, and took a course in medicine at the University of the City of New York. He graduated as a physician, and immediately afterward organized the College of Dentistry, to which, one year later, he added an infirmary. Of this institution he was made Superintendent in 1869. He was the author of many valuable treatises on dental and medicinal subjects, and was a member of several scientific and literary societies. He was an enthusiastic collector of rare prints relating to American history, and is said to have possessed the finest collection of its kind in this country.

CORRESPONDENCE.

AN UNUSUAL COMPLICATION OF EMPYEMA.

To the Editor of the MEDICAL NEWS.

DEAR SIR: I send you, herewith, the report of a case of empyema, following pleuropneumonia, which presented an unusual complication causing death.

Mrs. S., aged twenty-six. Family history negative. Previous health good. I first saw the patient January 20, 1897, in consultation. She had been ill for five weeks. I found her with a temperature of 101° F.; pulse, 140, and respiration, 48. The physical examination showed the right lung to be collapsed, with a considerable amount of fluid in the pleural cavity. There was a slight hypostatic involvement of the base of the left lung. The patient was coughing almost constantly, and expectorating pus by the mouthful, that smelled strongly of sulphuretted hydrogen. An exploratory puncture in the sixth intercostal space was made with an aspirating needle, and a pint of pus evacuated. This was followed by temporary relief of the cough. The diagnosis was empyema with perforation of the lung. An operation was advised, and the patient was brought to the hospital in a state of collapse. By means of oxygen inhalations and strychnin, administered hypodermatically, she rallied so that her condition was about the same as when I first saw her. Not deeming general anesthesia safe under the circumstances, I used the infiltration method. A free opening into the pleural cavity was made in the track of the previous needle puncture, from which pus was beginning to be discharged. Two drainage tubes were introduced, and the cavity drained freely. The next morning the temperature was normal, pulse 108, and respiration 32. The patient did well for forty-eight hours, when the temperature again became elevated, and the discharge from the wound was enormous, although it had lost its odor of sulphuretted hydrogen. In the discharge were many large coagula, resembling curdled milk in odor and appearance; so that a fistulous communication with the digestive tract was evident. A charcoal tablet was administered as a test, and the next morning it was washed from the pleural cavity. The patient died twelve days after the operation from starvation, not having been able to retain nutritive enemas, and nearly, if not all, nourishment given by mouth passing from the wound.

Autopsy.—Right lung completely collapsed, with numerous bands of adhesion between it and the chest wall. The pleural sac contained about twenty ounces of pus, mixed with food. The surface of the visceral pleura showed several sinuses leading into the lung tissue. At the nipple line was a point where the pleural covering of the lung was broken down, and a hernia of semidisintegrated lung tissue protruding. The stomach was opened, and water introduced by means of a fountain syringe was speedily discharged from the point above mentioned. Further dissection revealed a perforation through the lung into the side of the esophagus. The opening was circular and about one-third of an inch in diameter.

The left lung was adherent to the chest-wall over nearly the whole of its surface, and posteriorly showed signs of a beginning encysted empyema.

Very truly yours,
EDWARD B. PATTERSON, M.D.
MANISTIQUE, MICH, March 14, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

PATHOLOGICAL SOCIETY MEETING—THE COLLEGE OF PHYSICIANS' MEMORIAL TO THE SENATE—THE GROSS STATUE—KINGS COUNTY HOSPITAL APPOINTMENTS—THE WALTER GARRETT MEMORIAL BUILDING.

PHILADELPHIA, April 24, 1897.

THE Annual Conversational Meeting of the Pathological Society of Philadelphia was held on the evening of April 22d. Dr. Ludvig Hektoen of Rush Medical College, Chicago, delivered an address on "Segmentation and Fragmentation of the Myocardium." Dr. Hektoen expressed his belief that fragmentation and segmentation are two distinct processes, and that probably they occur independently, the former resulting from a loss of the intercellular cement substance of the muscular fibers. He also thinks that this lesion, which has been studied by himself and by others under varied circumstances, is capable of causing a fatal termination, and that it is the actual cause of sudden death in many instances in which there exists no demonstrable lesion. In his opinion, the capillaries of the heart, described by Meigs, are really instances of segmentation and fragmentation. Following Dr. Hektoen's address, he was tendered a reception by the Society at the University Club.

The College of Physicians is about to present to the United States Senate a memorial praying for the retention in the new Dingley tariff bill of the present law relating to the free entry into this country of books, instruments, specimens, and apparatus intended for institutions of learning. The College, with its magnificent library of over sixty thousand volumes, and its museum of pathology and surgery, fears that its usefulness will be greatly crippled should the existing law be altered.

The unveiling of the Gross statue in Washington on the fifth of next May will be an event of especial moment to the medical men of Philadelphia, and particularly to the alumni of the Jefferson Medical College, who have accomplished so much toward securing a fitting memorial to this once-distinguished member of their faculty. The trustees, faculty, and many of the alumni of this institution have arranged for a special train for the trip to the Capital on this occasion. The Secretaries of the Treasury and Navy have accepted invitations to be present at the ceremony, and it is hoped that the President will make an address. Letters from many European surgeons have been received by the secretary in charge of the proceedings, regretting their inability to be present, and expressing their highest appreciation of the services rendered to surgery by Dr. Gross. The ceremonies will be opened by a prayer by the Rev. B. L. Whitman, D.D., President of Columbian University, Washington, D.C.; the presentation of the statue is to be made by Dr. C. H. Mastin of Mobile, who initiated the movement of erecting the present memorial; the unveiling will be performed by a granddaughter of Dr. Gross, Miss Adéle Horwitz; Surgeon-General George M. Sternberg, U. S. A., will receive the statue on the part of the Government, and Dr. W. W. Keen of Philadelphia, the successor to Dr. Gross' chair in the Jefferson Medical College, will deliver an address. The statue, which is considered by those who enjoyed Dr. Gross' acquaintanceship an admirable likeness, is the work of A. Sterling Calder, a young Philadelphia sculptor of great talent.

That New York should look to her laurels is the inference drawn from the result of the recent competitive examination for resident physicians at the Kings County Hospital, Brooklyn, at which the first, third, and eighth places were won by graduates of the Jefferson Medical College. Out of a total of fifty-two applicants for the vacancies there were fifteen from Philadelphia, eight of whom were from the above-named school.

The latest addition to the group of new buildings which have been erected by the Pennsylvania Hospital during the past few years was formally opened on April 23d, with the dedication of the Walter Garrett Memorial Building. The President of the Board of Managers of the Hospital, Benjamin H. Shoemaker, presided at the exercises, and made a brief introductory speech. Dr. Thomas G. Morton, for many years a surgeon to the hospital, described the building and its uses, and gave an interesting review of the modern status of surgery. Dr. J. M. Da Costa, a member of the medical staff, paid a high tribute to the former physicians to the hospital, and mentioned in particular the special abilities of many. Dr. John B. Chapin, Physician-in-Chief of the Insane Department of the Pennsylvania Hospital, spoke of the development of this branch of the institution, and described the work of which he has charge. The ceremonies concluded with an inspection of the new building, after which a lunch was served to the visitors.

OUR VIENNA LETTER.

[From our Special Correspondent.]

EASTER VACATIONS IN VIENNA—FREQUENT HOLIDAYS IN THE AUSTRIAN UNIVERSITY—THE FIRST WOMAN TO RECEIVE A DOCTOR'S DEGREE FROM THE IMPERIAL AUSTRIAN UNIVERSITY—AMERICAN WOMEN MEDICAL STUDENTS IN VIENNA—CONSERVATISM IN APPENDICITIS.

VIENNA, April 7, 1897.

THINGS medical here in Vienna are very quiet just now. At the University the usual vacation between the winter and summer semesters is in progress, and professors are either away on a holiday or preparing quietly for the work of the next session. To an American, the occurrence of a six-weeks' vacation in the midst of the year's work seems, at first glance, to be utterly inadvisable. For us, of course, it would not answer, since it would involve the continuance of the work during the warm months. Here, however, where the heat is not a special source of inconvenience, at least not until late in July, the vacation must be a welcome break in the monotony of the ordinary routine. Holidays generally are much more frequent during the scholastic year here than they are in America. This seems to be the case not so much from deliberate forethought on the part of the University authorities as from the following of long-established usage in the matter; but one cannot help thinking that the system has its advantages. Intellectual work of a solid character is much better accomplished when broken by periods of complete relaxation than when the mental tension is maintained continuously for months at a time. It does not suit our impatient American ways, however, and not a little complaint is heard from American students here at the frequent, and what they consider unnecessary, loss of precious time.

Friday, April 2d, was, in the words of the *Rector magnificus* of the University of Vienna, "a day of special significance for the University, since on it occurred the giving of the first doctor's degree that our old and revered *alma mater* has ever conferred upon a woman." The degree was the Doctorate in Medicine, and the recipient was Gabrielle Possaner von Ehrenthal. The event marks an era in university education in Austria, and probably means the extension, in the near future, of all the Imperial University privileges to women. Considering the difficulties he had to overcome, the new sister in the profession thoroughly deserves the congratulations that she has received from all sides. She is a member of a noble Austrian family, and after preparatory studies here she continued her medical course in Zurich, as the University of Vienna was not open to her. After taking her degree, some four years ago, she applied for permission to practice in Austria, but was told that for that she must have an Austrian degree. This, of course, seemed impossible. Finally, however, she was granted governmental permission to practice in a part of the empire adjoining Turkey, and where the presence of a considerable number of Mohammedans would make her work somewhat that of a medical missionary among the unfortunate Turkish women. This privilege, as might have been expected under the circumstances, was not very highly appreciated, and her case was presented by influential friends to the Emperor himself. The well-known loyalty of her family and her own well-proven merits were enough to outweigh even the solid conservatism of Austrian institutions, and at the Emperor's request, after the usual examinations, the Austrian University's doctor's degree was granted. Coming in this way, one might have expected that the degree would have been conferred without any special *éclat;* but students and faculty were in heartiest accord in expressing the most cordial sentiments of welcome to the first sister it had been their privilege to greet.

The *Rector magnificus*, Professor Reinisch, after congratulating her on "the great energy and intelligence she had displayed in overcoming the obstacles that were in her path," said that he "was proud to hail her as the first victor in the contest for woman's intellectual rights in her native country." He added: "Man may think as they will of this important question of woman's rights, but every thoughtful and unprejudiced mind must admit that the broadening of the intellectual field of view of women will inevitably elevate the intellectual and moral standard of the whole race. We would commit a serious sin against progress if we were to confine such women as have distinguished themselves by their moral and intellectual power to the kitchen and to the nursery. It is to be hoped that what one woman receives now as a special favor will in the very near future be open to all women as a right. Wonderfully impressive words are these from a rector of the University of Vienna. They are an earnest of the time, not far distant now, when intellectual culture, whether far its own sake, or for any humane or utilitarian purpose, will nowhere be considered as the special privilege of one sex to the exclusion of the other.

The rector's address was received by the students present with impressive cheers ("*Prosit-Rufen!*"), and when the graduation exercises were over, and the newly "promoted" doctor surrounded by friends left the hall sometime after the other candidates, she was received by the students gathered in the corridors with the most cordial cheers and cries of "*prosit!*"

Despite the fact that women are not admitted to university courses in Vienna American women doctors have for fifteen or twenty years found it well worth their while to come here for advanced work. Not every opportunity that they might wish has been open to them, but their own sterling common sense, their readiness to work, their general appreciation of what was done for them, and, one must add, their thorough intellectual qualities, added more and more to their opportunities until now there is scarcely any privilege that they cannot have for the asking. Conservatism still has its hold, however, and to some of the professor' courses not even American doctoresses have been able to gain an entrance. It has not been because they have not tried hard enough, though. One wonders now whether after this graceful bow of the University authorities to the Imperial wishes this remaining exclusiveness will not finally vanish.

One of the striking things about attendance on surgical clinics in Vienna is the comparative absence of operations for appendicitis. In a large general hospital, where a number of cases are operated on each day in America, one would surely see appendicitis operations quite frequently. I venture to say that at none of our post-graduate schools, at least, does a week pass without an occasion being afforded to demonstrate that very fashionable procedure. At first one is inclined to welcome with unalloyed pleasure this failure to fall into line and to bless the thorough-going conservatism of the great surgical school that protects it from being carried away by the fancy of the hour. But the medal has its reverse, and the autopsy-room makes some impressive revelations. After one has seen on the *post-mortem* table some cases of perityphlitic abscess from ruptured appendices, with liver abscess from spread of infectious micro-organisms along the portal veins, and even abscesses of the lungs from further spread of the infecting material, one does not feel so kindly toward conservatism. Such cases must be extremely rare in America now, but here one is assured that they are often seen. Usually, of course, these patients come to the hospital in an inoperable condition, with the process so far advanced owing to medical neglect that surgical interference is not deemed advisable, but it is a cause for congratulation that the veriest country practitioner in America would not now allow a case to progress this far without rendering surgical assistance. Conservatism is all very well in its place, but when it comes to leaving untouched a collection of pus, the outlines of which can be easily traced on the abdominal walls beneath the edematous tissues that betray its presence, until it has infected other important organs, then it ceases to be a virtue. American surgeons may go too far in their enthusiasm to remove appendices, but that is surely not as bad as leaving them alone in the medieval style in vogue here.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

CASE OF TYPHOID FEVER FOLLOWING INGESTION OF OYSTERS—URETERO-PYELONEOSTOMY IN A PATIENT SUFFERING FROM HYDRONEPHROSIS—MASSAGE FOR FRACTURE OF THE CLAVICLE—TREATMENT OF A HYDATID CYST OF THE LIVER BY RESECTION OF THE INFERIOR BORDER OF THE THORAX—ACUTE ANGIOCHOLECYSTITIS CAUSED BY COLI BACILLUS, ETC.

AT the session of the Academy of Medicine held March 16th, CHATIN mentioned a case of *typhoid fever following the ingestion of oysters.* Investigation of the circumstances connected with the case revealed the fact that the oysters were grown in beds which were contaminated by the sewage of a large city. Several persons were made sick from eating these oysters, but only one died. In this instance, as well as in many similar ones which have been reported elsewhere, there was the grossest neglect of all precautions to produce healthy oysters. There is little danger of infection from oysters even when grown in unhealthy places if they are placed in pure sea water for a week before they are eaten. The sea water hinders the development of the typhoid bacillus and increases the resisting power of the bivalve.

At the session of March 30th, MONOD reported a case of *uretero-pyeloneostomy* performed by Bazy in a *patient suffering from hydronephrosis* due to defective opening of the ureter into the pelvis of the kidney. A free incision was made, the fluid evacuated, and the ureter divided and implanted low down in the pelvis of the kidney, so as to favor the escape of urine. Similar operations have already been performed a few times, and the tendency at present is to substitute some such plastic operation for nephrectomy in cases of hydronephrosis.

At the session of April 6th, LUCAS-CHAMPIONNIÉRE showed four patients who had been treated by *massage for fractures of the clavical* occurring thirteen, fifteen, eighteen, and nineteen days previously. In no case was there any pain, and the patients were able to move their arms in any direction.

PEAN said that massage was advisable in many fractures, but that it cannot take the place of the present methods of treatment in all cases; and that all the four patients presented a slight degree of projection and overlapping of the fragments, which would be very objectionable in the case of a woman.

CHIPAULT has treated seven patients suffering from perforating ulcer by stretching the plantar nerves, with but a single failure. In five cases both the internal and external plantar was stretched. Every effort should be made to cleanse the ulcer thoroughly by curettage, etc., and primary union of the wound, made for stretching the nerve, should be secured if possible.

In the Surgical Society, March 17th, RICHELOT describes a case of *peritonitis occurring in a girl aged 9 1-2 years as a result of a fall upon the stomach.* Four weeks later puncture of the abdomen produced 1.5 liters (three pints) of pus, and median laparotomy was performed. The bladder, which was adherent to the abdominal wall, was opened, but immediately closed by fine silk sutures, and three liters (six pints) of the thick pus, containing fibrinous masses, was removed from the abdominal cavity. The peritoneal cavity was washed out with a 1–10,000 bichlorid solution. The cul-de-sac of Douglas was tamponed with salol gauze by Mikulicz's method. A drain was also placed in each iliac fossa. The patient recovered.

RICHELOT objects to the use of the term "general peritonitis" in such a case as this for the pus was confined in the lower abdomen. Cultures of the pus, as well as inoculations, were negative, but the idea prevailed that the case was one of tuberculous peritonitis set up by the accident. He criticised the use of bichlorid solution for irrigation, and considered pelvic drainage better than the tamponing with gauze by the Mikulicz's method. Quéne and Reynzer were in accord with Richelot's opinion. Brun believed the case to be one of peritonitis, produced by a pneumococcus.

MONOD described *the treatment of a hydatid cyst of the liver by the resection of the inferior border of the thorax*, according to the method of Lannelongue. Incision was made through the eighth, ninth, and tenth costal cartilages, and by this means the superior surface of the liver was rendered easily accessible, even to its posterior border. By experiments made upon the cadaver, Monod determined that it is possible to resect the anterior and inferior portion of the thorax without touching the pleura. Beginning with the seventh costal cartilage, close to the sternum, one follows a line obliquely downward and outward to the chondrocostal articulations of the ninth and tenth ribs, and terminating about an inch behind the anterior extremity of the eleventh rib. If the incision be made exactly as described, the pleura will not be injured, and the convex surface of the liver will be fully exposed.

LEJARS presented a patient upon whom he had performed cholecystostomy for an *acute angiocholecystitis produced by the coli bacillus.* The symptoms presented were those of jaundice, acute pain, vomiting, and intense fever, without morning remission. The stools were scanty and pale. Bacteriologic examination of the fluid from the biliary fistula made the day of the operation gave almost pure cultures of coli bacilli. One month later the fluid from the fistula still contained only this one microbe.

At the session of the Medical Society of the Hospitals, held March 19th, MERKLEN mentioned *three cases of appendicitis occurring in the course of an attack of the grippe.* This is not a special form of appendicitis, and has no peculiar clinical features. The grippe, in fact, is no more than a predisposing cause which, by heightening the virulence of the germs normally found in the intestines, leads to an attack of appendicitis. In the three cases observed, recovery followed without surgical interference.

RENDU called attention to the difficulty of making a diagnosis of *appendicitis in hysterical subjects.* In two cases within his knowledge excessive and long-continued pain rendered the diagnosis of appendicitis almost imperative, but the physical examination was most unsatisfactory. In both cases removal of the appendix was followed by complete and lasting recovery, although the organ was only slightly congested.

Rendu thought that the pains caused by a low grade of intestinal inflammation were magnified in these cases by the hysterical nature of the patient.

TALAMON was unwilling to accept this explanation for all hysterical cases. He thought they should be placed in two classes, in one of which hysteria is the sole cause of the symptoms, and to which the name of *hysterical pseudo-appendicitis* should be applied; the other class of cases includes the two mentioned by Rendu, and should be known as appendicitis with hysterical peritoneal symptoms. In these cases, which often simulate tuberculous peritonitis, the existence of painful crises, the alternation of diarrhea and constipation, frequent vomiting, and sometimes a daily rise of temperature, renders the diagnosis extremely difficult.

At the session of April 2d MEUNIER presented the case of a child, aged eight years, who was admitted to the hospital with the obvious signs of acute tuberculosis. A few days later rose-colored spots appeared, the temperature, in the meantime, presenting the usual characteristics of typhoid fever. In spite of the absence of all intestinal phenomena, typhoid fever was suspected, and serum diagnosis was therefore resorted to on several occasions, invariably with positive results.

The autopsy showed the existence of typical miliary tuberculosis, the characteristic granules being found in the lungs, pleura, meninges, etc. The intestine was the seat of small ulcers, presenting all the characters of tubercular ulcers of the lenticular type, with gray granulations on the peritoneal envelope. Histologic examinations indicated that these were really tuberculous lesions, the walls of the ulcers swarming with Koch's bacilli. On the other hand, bacteriologic examination proved that the agglutination observed during life was the result of the presence of Eberth's bacillus, which was found in cultures in the splenic pulp and in the pulmonary and pleural liquids. There consequently could be no doubt of the typhoid infection, as indicated by the temperature curve, the eruption, and the result of the serum diagnosis, though it was completely overshadowed by the evolution of acute phthisis.

At the session of the Therapeutical Society, held March 24th, BARDET read a paper on the treatment of chlorosis and anemia, in which he stated that the therapeutic value of iron varies according to the preparation employed and the special condition of the patient. Everything depends on the absorption which itself is dependent on the digestion; and as digestion is an extremely complicated chemic phenomenon, varying with each individual, it naturally follows that a given preparation may be valuable in one case and worthless in another. Dujardin-Beaumetz employed by preference those preparations of iron which most closely resemble the iron found in the body, hemoglobin among others. These preparations are well borne by the stomach, and ingestion is the only rational method by which to administer them. Iron glycerophosphate appears to be a very good preparation, but it does not keep well. This difficulty may be overcome by giving a preparation of iron concurrently with calcium glycerophosphate.

ROBIN said that the examination of the chemistry of the metabolic changes in anemia leads to a division of these cases into two classes. The first and more important of these comprises anemic patients with diminution of the nitrogenous changes and oxidation. The second group includes anemic subjects in whom the oxidation and the nitrogenous changes are increased. Iron increases the oxidation to a marked degree, while arsenic, on the contrary, exerts a powerful moderating influence on this process. The indications for the use of one of these drugs are consequently exactly the opposite of those for the use of the other.

DALCHE reported a case of slightly albuminuric diabetes, in which four hypodermic injections of one gram (fifteen grains) of caffein in twenty-four hours produced serious cerebral disturbances, excitement, delirium, etc. In the absence of other plausable explanation, it must be assumed that the patient possessed a special idiosyncrasy for the drug.

LE GENDRE called attention to the fact that small doses of caffein, or even of black coffee, may cause disturbances of this kind.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting held April 6, 1897.

THE President, B. SACHS, M.D., in the Chair.

THE STATE OF THE REFLEXES IN SUPRALUMBAR LESION OF THE CORD.

DR. JOSEPH FRAENKEL, read a paper on this subject. He said that it was a general clinical rule that interference with the conduction of the spinal cord leads to an increase in the reflex activity of the centers in the cord below the lesion. The following illustrative cases were cited:

CASE I.—A patient, sixty years of age, entered the Montefiore Home fourteen months after the onset of paralysis of the lower extremities. During the first six months he suffered from sharp darting pains in the lower extremities. Extensive bedsores developed during the last four months of life. The examination showed total motor and sensory paraplegia. There was no tenderness over the spinous processes, and no localized atrophy. The autopsy revealed caries of the bodies of the eighth and ninth dorsal vertebræ, with great thickening of the dura at this level, and with adhesions to the vertebræ for about three inches. The cord was markedly softened, and the microscope showed extensive changes, mainly of the nature of myelomalacia. Above the lesion there was secondary degeneration of the columns of Goll; below the lesion, secondary degeneration of the pyramidal tracts. The process was probably tuberculous.

CASE II.—A woman, twenty-one years of age, entered the hospital on account of transverse myelitis. The disease had developed without assignable cause nine months previously, but she had not sought relief until the involvement of the bladder. Six months after the appearance of the first symptom, she was completely paraplegic. The examination showed marked anemia, a temperature of 102° F., and an extensive bedsore over the sacrum. There was no atrophy; the lower extremities were decidedly tender, and were flexed at the hips and knees. There was total motor and sensory paralysis of the lower extremities, and loss of reflex activity, yet on tickling the soles of the feet they were drawn up. The autopsy showed a fistula at the level of the eighth dorsal vertebra leading into the spinal canal, and a very vascular sarcoma the size of a cherry, which had pressed upon and softened the tenth and eleventh dorsal segments. The microscope showed that some healthy fibers kept up the continuity of the cord.

CASE III.—The patient was forty years of age, and had a good personal and family history. Up to two weeks before admission his disease showed the familiar symptoms of marked pulmonary tuberculosis. At this time, the spinal cord became involved in the process. The examination showed the temperature to be 101° F. There was an extensive tuberculous process in each lung, and the spinal cord was tender from the lower dorsal region downward. The patient was greatly emaciated, but there was no localized atrophy. The gait was uncertain, apparently due to imperfect coordination. There were numerous areas of anesthesia and analgesia. All superficial reflexes were present, but somewhat diminished. Fairly good contraction of the quadriceps tendon could be *felt* on tapping the tendon, but it evoked no locomotion. Five days after admission, motor paralysis was found to be more extensive, and the bladder was beginning to be involved. The patellar reflex was much diminished. Shortly after this the patellar reflex disappeared altogether, and a bedsore developed. The *post-mortem* showed advanced tuberculosis in both lungs, and a pachymeningitis extending from the seventh to the tenth dorsal segments. The cord was very much softened in this region, and the microscope showed a fair number of healthy fibers. The lumbar cord was normal.

CASE IV.—This was in a boy whose trouble had developed immediately after a severe fall. On admission, the extremities presented a peculiar swollen appearance, and pitted slightly on deep pressure. There was a large bedsore over the sacrum. The temperature was 103° F., respirations were abdominal, the urine contained considerable albumin, the pupils were unequal, and the abdomen was very tympanitic. There was hyperesthesia in the upper part of the trunk, and total anesthesia below. The temperature sense was perverted. The muscles were in a state of complete flaccidity. There was total motor and sensory paralysis. When the soles of the feet were tickled the limbs were drawn up. At the autopsy the sixth, seventh, and eighth dorsal segments were found to be replaced by a fibrous band.

The foregoing cases, Dr. Fraenkel said, showed that occasionally lesions of the cord above the lumbar region did not cause loss of the reflexes. He had found reports of ninety new cases, representing a variety of pathologic conditions, distributed in widely different parts of the cord. In the old cases there was absolute loss of motility. When the continuity of the cord is completely interrupted this can be easily understood, but not so when the interruption is only partial. It seemed reasonable to infer that the motor fibers were always the first ones to suffer in a pathologic process. Sensibility was absolutely lost in all cases where section of the cord was complete. The fibers which served to conduct deep sensibility seemed to have a more specialized function, and were probably the ones most prone to suffer, next to the motor fibers, when the cord was subjected to pressure. In nearly every case it was stated that the sphincters were paralyzed. In fifty-one reported cases, and in one of his own, there was total destruction of the continuity of the cord, and in all the lesions were such as to indicate serious injury to the cord. In his opinion, Bastion's theory seemed to have met with the most general acceptance. The exact nature of the knee phenomenon was not definitely known. We know positively that the influence exerted by a higher center can inhibit the reflex, and it seemed reasonable that this superior influence should run in an arc. The centripetal branch of this arc exists in some of the ascending columns of the cord to which no definite function had yet been allotted. It should be remembered that loss of the knee-jerk in supralumbar lesions was not necessarily a matter of importance in prognosis.

DR. M. ALLEN STARR said that he had just been reading a paper, by Kocher of Berne, covering to some extent the same ground. He reported seventy cases of transverse lesion of the cord, and made very positive statements to the effect that loss of the knee-jerk is absolutely diagnostic of total ablation of the continuity of the cord above the lumbar region. Many neurologists doubt the validity of the above proposition, and hence the paper just presented is particularly timely. Bastien's statements have provoked criticism from many quarters. This paper admits the possibility of a transverse lesion in some cases causing exaggeration, and in other cases, a loss of reflexes. While this might not satisfy our theories, it is an important contribution of facts.

DR. ONUF said that Dr. Fraenkel had called attention to the *rôle* played by the cerebellum in the production of the knee-jerk. We know, further, that the pyramidal tracts have an inhibitory influence on the knee-jerk. He desired to advance a theory in this connection. We have not been able to explain many physiologic facts except by assuming the influence of so-called inhibition. One important example of this was to be found in the pyramidal tracts, particularly in those fibers passing from the cortex directly to the anterior horn cells. So far as he knew, no one had tried to supply an anatomic basis for inhibition in order to explain the occurrence of excitation in one case, and inhibition in another. Dr. Onuf said that he assumed that when a current from a cell passes from the protoplasmic process toward the nerve process, or from the cell-body to the nerve process, excitation of the cell results. If, on the contrary, the current passes from the axis cylinder or nerve process towards the cell body, inhibition is the result. These connections are not entirely theoretical—they have been actually demonstrated. He also assumed that the axis cylinder of the pyramidal fiber ends with the terminations around the axis cylinder of the anterior horn cell. The pyramidal fibers have not only an inhibitory influence on the knee-jerk, but their function is in general, not a motor, but an inhibitory one. He would say that voluntary excitation takes place through the cerebellum, and that the direct cortical spinal fibers have only an inhibiting influence. A case of absolute paralysis in connection with degeneration of the pyramidal tract has never been reported. By assuming a motor pathway, this inhibition would be found very important in finely graduating movements. We know nothing definite about the mode of termination of the fibers around the peripheral neuron. According to the theory just propounded, a complete transverse lesion, interrupting the pyramidal tracts, should cause loss of the knee-jerks. Interruption of the motor cerebellar spinal pathway should cause complete loss of the knee-jerk, for the peripheral stimulus is counteracted by the inhibitory influence of the pyramids. One fact agrees very well with this theory, *viz.:* the degeneration of cortical spinal fibers (pyramidal tracts) frequently associated with degeneration of the anterior horn cells.

DR. C. L. DANA said that Dr. Onof's theory was very ingenious, but it was open to criticism, which, however, should not be made until after further consideration. The views of Dr. Fraenkel seemed to him very similar to those of Dr. Onuf, and they were certainly very plausible. The chief problem presented was to explain those cases in which the knee-jerks are absent, and yet in which the transverse division of the cord is not complete.

DR. E. D. FISHER asked Dr. Onuf if the pyramidal tracts were no longer to be considered as motor tracts, but rather as simply inhibitory tracts.

DR. ONUF replied that the pyramidal fibers are not the motor tracts in the sense in which we have hitherto considered them. There must be at least this motor pathway, although there might be another one, through the pons, for example. When we stimulate the cortex the fiber which gives the motion is the one which passes into the pons and cerebellum and into the cord.

DR. FISHER asked why, then, with absolute destruction of the cerebellum, as had been done experimentally, we do not get absolute paralysis.

DR. ONUF replied that *all* of the cerebellum had not been extirpated in these experiments. He did not claim that the only motor pathway was through the cerebellum, but that there must be another motor pathway than the pyramidal tract.

DR. C. A. HERTER said that the cases reported by Dr. Fraenkel were very valuable. His experience certainly showed that it was possible to have a complete abolition of the patellar reflex with a partial transverse lesion of the cord above the knee-jerk center. His own impression, gained from clinical observation and from a perusal of the literature, had been that we are justified in regarding a loss of the knee-jerks in consequence of a transverse lesion high up in the cord as an evidence that that transverse lesion is a complete one. He was disposed now to think that we had perhaps been rather hasty in considering this a final conclusion. While he had some hesitancy in throwing aside the theory of the motor function of the pyramidal tract, he believed the theory presented by Dr. Onuf embodied certain valuable suggestions.

DR. JOSEPH COLLINS said that he had been particularly gratified with the paper, because when a few months ago he had ventured the statement before the Society that in cases of incomplete transsection of the cord there was sometimes absence of the knee-jerk; it was said in the discussion that this must be an error of observation. The theory that Dr. Fraenkel had proposed concerning the occurrence of the reflexes presented some anatomic difficulties. While the theory that the fiber conducts impulses in the direction in which it degenerates was no longer tenable, it seemed to him that, as a general rule, it was true. He thought we must assume some influence operating contemporaneously with the cerebellum to explain the reflexes, and possibly some function of the somesthetic area was at work, at least the explanation of "reinforced reflexes" suggested that. This was very much in accordance with the theory promulgated by Dr. Onuf. He did not think any one to-day holds that the motor tracts are absolutely and only motor. The facts of infantile cerebral palsy show that defects of the somesthetic area are not always accompanied by paralysis, if we were not in possession of much evidence of the same kind from other sources.

Dr. Starr queried if it would militate against Onuf's theory if it were considered that the pyramidal tracts are developed in animal life exactly in accordance with the development of the digital extremities. Dr. Spitzka has shown that in the seal, walrus, and elephant, the pyramidal tract is practically wanting, and develops in accordance with the motility of the digits. This fact was interesting in connection with Onuf's theory.

The President said that in spite of all the facts brought out the cases under consideration were, after all, exceptional. Granting that in the complete lesion of the cord above the lumbar level the knee-jerks are abolished, there have certainly been a number of other cases in which, although the lesion was tolerably complete, the functions were not entirely lost. In Pott's paralysis it is a common thing for the knee-jerks to be exaggerated. He had had an autopsy in a case of dorsal Pott's disease in which the cord was completely softened, yet the knee-jerks instead of being lost were exaggerated from beginning to end, and there were also contractures. For these reasons it did not seem to him wise to build up theories to explain exceptional cases. We would all be compelled to abandon the theory that the pyramidal tract conducts motion only, or chiefly. There is a fair foundation for the view that there is one corticospinal tract, and one cerebellar tract. After an examination of a large number of cases of spastic palsies, in both adults and children, he had found very few cases in which there was no paralysis. He felt positive that these cases had more paralysis than spasticity or rigidity.

Dr. Onuf said that the pyramidal tracts have been found to be absolutely absent throught the whole cord in a fetus of seven or eight months. This fact has been quoted to explain those cases of Little's disease in which there is no cerebral disease, and no paralysis, but only rigidity. It also tends to confirm the view that the pyramidal tracts are not strictly motor pathways.

Dr. Fraenkel, in closing, said that he did not doubt that any supralumbar disease of the cord will produce spastic paraplegia, but when there is a mechanical and pathologic condition interferring progressively with the conducting function of the cord, and sufficient to give motor paralysis, the knee-jerks will be lost. Where there is a total anatomic destruction of the cord, the reflexes are abolished, probably because of the cutting off of the cerebellar influence passing through the columns of Gowers. In a few of the recorded cases there was only partial destruction, yet the knee-jerks were lost as soon as the deep sensibility fibers were destroyed.

NOTES ON SOME ANATOMIC CHANGES IN THE BRAIN-CELLS IN ACUTE ALCOHOLISM.

Dr. Charles L. Dana, read a brief paper with this title, reporting ten cases, and the results of his studies in this direction during the past two years. He had used Nissl's stain for the most part. He stated that what was ordinarily known as acute alcoholic meningitis could not be said to be a meningitis at all, although clinically these patients died with all the symptoms of meningitis. The autopsy reveals simple congestion and edema of the brain, and even the microscope but rarely shows any migration of leucocytes or anything approaching encephalitis. In some cases, not even vascular activity will be observed. Alcoholic meningitis is not primarily a vascular disorder, but a slow poisoning; hence, we must study the cell to determine the changes produced. It has been stated by some investigators that all forms of cell degeneration are the same, and that it is impossible, as Nissl claimed, to make out different cell degenerations in accordance with the particular pathologic irritant. Whether this is so, or not, certainly the microscopic appearances are different in different cases of alcoholic meningitis, and in other cases associated with delirum and acute disorder prior to death. There is one type of degeneration quite characteristic of those dying from sunstroke, with intense delirum and very high fever. It consists in a distinct and general pigmentation, involving the larger cells. This sudden development of pigmentary degeneration would seem to be characteristic of acute febrile degeneration, associated with acute toxemia. Another kind of pigmentary cell degeneration was found in a case of pernicious anemia. Here, the pigmentation involved both the small and large cells. In a case of prolonged use of morphin and whisky, in which death was due to exhaustion and malnutrition, the brain showed quite a general atrophy of both the nuclei and the cell bodies. There are three types of cell degeneration, *viz.:* (1) Intense pigmentation of the larger cells, chiefly with degeneration of the cytoplasm; (2) a general cell atrophy of the body and nucleus; and (3) a good deal of change in the cell-body, with many neuroglia nuclei in the pericellular spaces. In the cases of alcoholism and alcoholic meningitis it was not possible to made out a distinct type of cell degeneration, nor could this be expected, as these patients die not so much from the alcohol as from autotoxemias, and from the febrile process.

A CASE OF MENINGITIS SEROSA ACUTA.

Drs. C. A. Herter and Ira Van Gieson reported a case apparently coming in this category. The patient was a man, thirty-three years of age, who had enjoyed good health up to a year before his admission to the hospital. While in the hospital he suddenly developed coarse clonic spasms. The feet were habitually in extension, and there was slight clonic spasm in the flexors of the thigh. There was extreme and constant deviation of the head and eyes to the right. The spasms in the arms and legs were fairly symmetrical. The pupils were equal, of moderate size, and reacted fairly to light. The pulse was slow, of high tension, and fairly regular; the respirations were stertorous. On the following day the right arm was rigid, and the left relaxed, and the coarse flexor spasm had disappeared. Then a hemiplegia developed on the left side; the pulse was rapid, feeble, and of low tension. Toward the close of the day the patient could be aroused to partial consciousness. On the third day the irregular coarse spasms of the muscles began again, and were most marked at this time on the left side instead of on the right. The right pupil was dilated. On the fourth day the condition was essentially the same, but toward evening the irritative symptoms were less marked. On the fifth day, all spasmodic movements ceased, and the patient remained comatose until death occurred. The temperature had been only moderately elevated. The autopsy was made by Dr. Van Gieson. He found over the entire frontal and central lobes a thick layer of fluid between the pia and the surface of the brain. The pia was milky, thickened, and opaque. In the occipital and temporal regions this membrane was quite normal. The fluid was most abundant in the frontal region, but was nearly uniformly distributed over the whole center. The vessels and pia mater of the base were normal. The substance of the brain was pale, and the convolutions only slightly flattened. Microscopic examination showed the vessels of the pia to be largely obliterated. This effusion appeared to have occurred at the time of the onset of the acute symptoms. Probably the hemiplegia was due to pressure on the cortex. A similar case had been reported in which the effusion had apparently been due to an infection.

Dr. Dana said that he had seen quite a number of cases of alcoholism presenting an almost identical pathologic condition, although such a serious condition of the brain was not the rule in alcoholism. The clinical symptoms, however, did not permit of a differential diagnosis, nor did they indicate a sudden effusion.

Dr. Starr said that in operations on the brain, a varying amount of fluid would be found under the pia, irrespective of the lesion present. Slight manipulation of the brain by the surgeon would cause a disappearance of this fluid. For this reason he did not think much stress should be laid upon similar pathologic findings.

HEMORRHAGE INTO THE LATERAL VENTRICLES OF A NEWLY BORN INFANT.

Dr. Herter presented a specimen illustrating this condition. The child had been born at six months, and had lived in an incubator for a week. Labor had been difficult, but without forceps. A day or two before death extreme flexion of the toes and right index finger had been noted together with a general and marked icterus. The autopsy showed nothing abnormal except in the brain. In the latter was a hemorrhage which accurately filled both ventricles.

The President remarked that hemorrhage into the brain had been reported as having occurred at some period of fetal life.

REVIEWS.

Reference-Book of Practical Therapeutics. By various authors. Edited by Frank P. Foster, M.D. Two volumes. New York: D. Appleton & Co., 1896.

This is one of the most practical books on therapeutics that has appeared in recent years. It is especially designed for practising physicians, devoting its chief attention to therapeutics, and only regarding the physical properties of drugs in so far as these may have more than a pharmaceutical interest. Thus, the busy practitioner is saved a good deal of time, by not being compelled to wade through a mass of, to him, unimportant data connected with the physical properties and minerologic and botanic relations of the various drugs.

The authors who have assisted in this work are for the most part teachers of therapeutics in the various institutions of the country, and are specially noted for inculcating the facts that nihilism in therapeutics is inimical to medical progress, and is unscientific.

The various remedies treated are arranged in alphabetical order, making this work one in which reference is easy.

Some of the articles are more elaborately treated than others, and not always commensurate with their importance. As a rule, however, much-used therapeutic remedies receive the most attention at the hands of the various authors.

The reviewer may justly say that this work will be of very valuable assistance to every practising physician who employs it, for it embodies all the recent discoveries in practical and physiologic therapeutics; gives the most important therapeutic features and indications for the use of the various remedial agents, and this in a form so readily accessible that it is worth, in the saving of time, more than the cost of the book.

It is almost needless to say anything about the typographic features or the binding. The name of the publishers is its best recommendation in this regard.

Skiascopy and its Practical Application to the Study of Refraction. By Edward Jackson, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic, etc. Second edition. Philadelphia: The Edwards & Docker Co., 1896.

The appearance of a second edition of this excellent manual shows that more general interest is being taken in the practical application of the shadow-test to the determination of ametropia, as well as in the theoretical study of the procedure. The advantage of skiascopy, its objectivity, accuracy, and rapidity have long been recognized. The lack of a good handbook was, however, an important factor in preventing its general adoption. Jackson's work, while concise and clear, is based on scientific principles, and shows the practical grasp of the subject due to experience with its working methods. The use of both the plane and the concave mirror is explained with reference to graphic representations in each case.

ADAPTATION IN PATHOLOGICAL PROCESSES.[1]

BY WILLIAM H. WELCH, M.D.,
OF BALTIMORE.

ADAPTION in pathologic processes has the broadest biologic as well as medical interest. By the epithet "adaptive" it is intended to describe those morbid processes that bring about some sort of adjustment to changed conditions due to injury or disease. While it has been contended that the conception of adaptation has no place in science, I believe that natural phenomena must be investigated with regard to the meaning or idea which they represent.

From physiology we learn that the most wonderful and characteristic attribute of living organisms is their capacity for adaptation to external and internal conditions in a way tending to the welfare of the individual or species. Apparently these countless adaptations are full of purpose. So far as the existing order of nature is concerned, this theory is the foundation in forming a working biologic hypothesis. This seems an explanation of organic evolution. Physiologic adaptation occurring in organic evolution gives us the keynote to pathologic adaptation.

It is my opinion that those vital manifestations known as adaptive and compensatory are the necessary results of the energy inherent in living matter. The final result in no way directly influences the chain of events which leads to its production, nor does the character of the result in any way explain the mechanism.

Reviewing the history of the knowledge which we possess regarding protective processes and the methods of study by which this knowledge has been obtained, our attention is called to the importance of the new fields of research styled the mechanics of organic development and physiologic or experimental morphology.

One of the most interesting characteristics of pathologic adaptations is their foundation in physiologic processes—a fact of fundamental significance. Variation, natural selection, and heredity have in no direct way influenced pathologic adaptations. As an illustration of the foregoing, an individual born with exclusive capacity for cardiac compensation could not perpetuate such a variation through the survival of the fittest unless heart lesions became common to the species. Contrasted with the perfection of physiologic adjustments, pathologic adaptations are markedly imperfect. The cells of the body are its only means of protection from outside attacks or in restoring its damaged parts, but their fitness for this function comes primarily from physiologic properties. Cardiac compensation is never perfect; renal hypertrophy never produces a healthy organ. The most striking example of such imperfection is found in the excesses, disorders, and failures incident to inflammation. The preeminent examples of pathologic adaptation are the compensatory hypertrophies, the regenerations, and the protective processes, including parasitic and antitoxic phenomena, with some manifestations of inflammation and fever as well as changes in internal secretions. Chief among compensatory hypertrophies are those recognized as work hypertrophies. To complete our understanding, we must know the nature of the disturbances caused by the underlying morbid conditions, how they excite increased activity, and what the relation is between this activity and the growth of the part. In the present state of our knowledge, in no instance can these requirements be completely met. This statement is again illustrated by the study of cardiac hypertrophy. In general, I believe that cell-growth attending work hypertrophy must start from physical or chemical changes in the muscle or gland cells, and is directly connected with increased function. Increased supply of blood or lymph is not a determining factor. The final result is the necessary consequence of the underlying morbid condition. We possess a satisfactory mechanical explanation for the essential steps in the process, and there is no reason to assume that other than mechanical factors are concerned in those manifestations not explained by known physical or chemical forces. Cell properties which determine the character of their response to changed conditions, are their well-known physiologic properties. The adaptation resulting is imperfect and not a complete compensation. Vascular hypertrophy and pathologic changes well exemplify the propositions stated. This is seen to great advantage in the study of the placenta and embryo.

Of paramount interest at the present time is the application of these conclusions to the study of inflammation. This still remains an unsettled question. Between purely clinical and purely pathologic and experimental views, antagonism exists. From the clinical standpoint, inflammation is harmful. The pathologist and bacteriologist find in its phenomena a struggle for self-preservation. Modern knowledge teaches that the response of the cells in inflammation is made necessary and inevitable by their innate properties. Some of these protect them in mechanical and other injuries. As a whole, inflammation is an adaptive pathologic process without special fitness to justify us in extravagant statements upon this subject.

---

[1] Abstract of presidential address delivered before the Congress, May 5, 1897.

In conclusion, I wish to emphasize the fact that the healing power of Nature is often, under the circumstances present in disease, most incomplete and imperfect. Treatment based upon the idea that Nature is doing the best thing possible and should not be interfered with, rests often on an insecure foundation. In the light of modern knowledge, there is ample scope for the intervention of the physician and surgeon.

LESIONS OF THE RETINAL VESSELS, RETINA AND OPTIC NERVE, ASSOCIATED WITH GOUT.[1]

BY CHARLES STEDMAN BULL, M.D.,
OF NEW YORK.

AT the meeting of the American Ophthalmological Society held in 1893, the writer presented a paper on "Gouty Retinitis and Neuro-Retinitis," in which he gave a somewhat detailed *résumé* of our existing knowledge of the changes produced in the vascular system by the influence of the gouty diathesis. For a full account of these changes, and of the investigations of various observers in this direction, he would refer to the above paper, which was published in the "Transactions of the American Ophthalmological Society" for that year. In the four years which have elapsed since the paper was published, the conclusions which the writer then reached have been strengthened, and he can speak still more positively of the changes in the retina and optic nerve, and in the retinal vessels, which are not infrequently met with in gouty patients.

The pathologic condition of the blood in gout does not always manifest itself in a way that readily attracts attention, and this is particularly true in regard to the eye. Most authors who refer to retinal complications, occurring in the course of gout, mention only a hemorrhagic retinitis as being the most frequent retinal complication. I do not think that there is any doubt as to the existence of a gouty retinitis or neuroretinitis, which strongly resembles certain types of syphilitic retinitis, and which may or may not be accompanied by retinal hemorrhages and opacities in the vitreous humor. The occurrence of retinal hemorrhages is easily explained, for it is well known that gouty persons are prone to hemorrhages, venous obstruction, and irregularities of the circulation, due to great arterial pressure and a relaxed condition of the vascular walls; vitreous opacities may be present in these cases. Such hemorrhages may involve one or both eyes, and are of sudden onset. Small linear and flame-shaped extravasations of blood may be scattered all over the fundus. At the same time, the optic discs may be hazy, and the retinal veins engorged and tortuous.

The effects of the poison of gout upon the vascular system are: (1) A high blood pressure in the arteries; (2) hypertrophy of the left ventricle; (3) hard incompressible arteries undergoing atheromatous degeneration.

The influence of gout in the development of arteriosclerosis and endarteritis is now well-established. Arterial degeneration is hereditary in certain gouty families, and signs of arteriosclerosis are very often the first symptoms of the hereditary malady. Most of our knowledge of this condition of the arteries has been gained from Thoma's investigations, and we now recognize the fact that arteriosclerosis is caused by some general disturbance of nutrition, which is partly the result of infection, intoxication, and other pathologic lesions as yet but little understood, and partly the accompaniment of senile changes. We learn from Thoma that gout may be looked upon as the remote antecedent of endarteritis, and that the latter condition is by no means always reached through the medium of interstitial nephritis.

Changes in the constitution of the blood current, such as are met with in gouty patients, would be very likely—in fact, almost certain—to develop obstructive circulation in the capillary system. This condition of the capillary circulation must cause some change in the blood current in the arteries. Whenever the current is slow, the middle coat of the artery usually contracts, and when this does not occur, a new growth of connective tissue is developed in the tunica intima, which thus reduces the arterial caliber. The muscular coat of the artery first becomes involved, and the loss of elasticity permits the artery to dilate. As a result, the blood current becomes slow, the vasa vasorum are distended, and a new growth appears in the intima, and is followed by the same process in other coats. A similar condition is met with in the veins, and, in fact, the phlebosclerosis or endophlebitis may precede the endarteritis sometimes by a lengthy period. Both these conditions, endarteritis and endophlebitis, are found much more frequently in the retina of persons who suffer from chronic, non-inflammatory, atypical gout than in those who are afflicted with the typical inflammatory form of the disease, and the same thing is asserted to be true of the types of interstitial nephritis. One of the results of this retinal endophlebitis is edema of the retina, which is one of the constant symptoms in the early stages of the disease. The circulation may become reestablished through the obstructed vessels, in which case this edema disappears; but if the obstruction to the blood current becomes permanent, the distant venous branches become dilated, and in places varicose. The hemorrhages which are met with are due to local softening of the vascular wall, or to the rupture of these minute varicose dilatations. They may be of all shapes and sizes—small and punctate, linear or flame-shaped—and may be scattered all over the fundus.

---

[1] Read at the Fourth Triennial Congress of American Physicians and Surgeons, Washington, D. C., May 4, 1897.

The scope of this paper is limited, and is confined to a consideration of the changes in the retinal circulation, in the retina itself, and in the optic nerve, as seen with the ophthalmoscope. The literature on the subject is very scanty. None of the older authors mention retinal complications in gout, and until very recently none has been made of any changes in the retinal vessels. Gauté (*Thesè de Paris*, 1881) speaks of a gouty retinitis resembling syphilitic retinitis, which may or may not be accompanied by opacities of the vitreous and retinal hemorrhages. Lychon (*Thesè de Paris*, 1885) mentions neuroretinitis and intra-ocular hemorrhages as being due to gout. Nettleship ("Diseases of the Eye," fourth edition, 1890) says: "Hemorrhagic retinitis is more commonly met with in gouty persons than in others. It may be uniocular or binocular. The children or descendants of gouty persons, without being themselves subject to gout, are liable, in early life, to this insidious form of eye disease." This view is confirmed by Jonathan Hutchinson. Gowers ("Medical Ophthalmoscopy," 1890) speaks more positively in regard to retinal lesions in gout. He thinks that the characteristics of these cases are a greater degree of disturbance of vision than corresponds to the visible changes in the fundus, the tendency to irregular defects in the field of vision, and the presence of lesions of the retina and optic nerve of the other eye induced by a symmetrical morbid process. Galezowski (*Annali di Otalmologia*, XIX.) believes that the changes begin in the retina and extend to the choroid, giving rise to a retinochoroiditis, characterized by an alteration in the vessels and deposits in and outside their walls. All around the macula and along the vessels are brilliant patches of exudate. The inflammatory process occupies the central zone of the fundus, develops slowly, usually involves both eyes, and never ends in total blindness, as the periphery of the retina is rarely affected.

In the *Bericht der 25ten Versammlung der Ophthalmologischen Gesellschaft*, Heidelberg, 1896, Wagenmann has a very interesting article on "Eye Diseases in Gout," in which he admits that the diagnosis is not always easy in cases of atypical gout. After a careful study of the subject, he is convinced that the blood current containing an excess of urates irritates and inflames the tissues; or else the uric acid and other products of animal combustion are extravasated in minute quantities in the tissues. The inflammatory process may be so marked that relatively large deposits appear in the tissues. The origin of these deposits in the eye is best explained by the Ebstein theory, according to which the blood with excess of urates sets up an inflammatory process in places where the circulation is slow. The well known changes are seroplastic inflammation, and a deposit of what Wagenmann calls "concrements." This is undoubtedly the cause of the patches of exudation, the numerous small hemorrhages, the narrow arteries, and the marked venous hyperemia seen in the retina, and also of the recurrent vitreous opacities, which are often of a distinctly hemorrhagic character. In the discussion which followed this paper of Wagenmann, Nieden, in agreeing with the author of the paper, stated that he regarded the recurring retinal and vitreous hemorrhages as almost pathognomonic of gout. Pflüger and Hirschberg also endorsed the views entertained by Wagenmann, and the latter called special attention to the presence of glistening inorganic deposits in circumscribed patches irregularly arranged around the macula lutea in gouty patients.

In my paper, previously referred to, the detailed clinical history of five cases, and the reports of two autopsies, were given, with the results of the microscopic examination of the retinæ and optic nerves. In the four years which have elapsed since that time, I have added to my data on the subject the histories of ten other cases, with the report of one autopsy.

The lesions to which I wish to call the attention of the Congress are: (1) The changes in the walls of the blood-vessels of the retina, choroid, and optic nerve, including arteries, capillaries, and veins. (2) Retinitis of a peculiarly localized character, confined to the posterior zone of the fundus, with or without hemorrhages in the retina and vitreous, and characterized by a peculiar yellowish exudation, occurring in clearly defined patches. (3) Optic neuritis, generally with, but sometimes without, an accompanying retinitis.

The clinical history of the ten additional cases, on which this paper is based, resembles very closely that of the five original cases reported in the first paper, and the main facts are briefly repeated here. The subjective symptoms consisted in a deterioration of the vision, at first for small-sized type, but later for all objects at any distance, and a certain degree of photophobia, most marked for artificial light. The ophthalmoscope shows more or less marked blurring of the outlines of the optic discs, resembling the first stage of papillitis, but without the edematous swelling. The retinal arteries are diminished in caliber, in some places the lumen being reduced to the merest thread, and requiring the closest examination to see the minute blood column that still exists. The white lines along the vessels, both arteries and veins, are broad and distinct, and extend from the center of the papilla well out toward the periphery of the fundus. Occasionally the veins in places seem dilated like a fusiform aneurism, the vessel on both sides of the dilatation being reduced in caliber. Yellowish-white patches of exudation, at first brilliant but subsequently becoming dull, of varying size and shape, are seen grouped mainly about the region of the macula and disk, but with no systematic arrangement. These patches of exudation are entirely in the inner layers of the retina, as proved by the microscope. If hemorrhages are present, they are linear or flame-shaped in character, occur close to the vessels, both arteries and veins, and while mainly grouped around the posterior pole of the eye, are sometimes found scattered all over the fundus. If opacities of the vitreous are present, they are of the floating variety, are small and of varying shape, and may be either the result of previous hemorrhages, or an evidence of coexisting choroiditis. The ophthalmoscopic picture in these cases is that of general retinal angiosclerosis, with the addition of the glistening patches of exudation in the retina.

These patients had all shown signs of extensive degeneration of the walls of the blood-vessels throughout the body, notably in the temporal and radial arteries. Their urine was usually of moderately high specific gravity, ranging from 1020 to 1026. It was loaded with uric acid and phosphatic acid crystals. I have occasionally found a little albumin, but never any sugar or casts.

Of the five patients whose cases were originally reported, two died previous to the presentation of the first paper, and the results of the autopsies have been published. Since then two other patients have died (Cases II. and III.), both of cerebral hemorrhage. The other patient (Case I.) is still living, and possesses enough vision to assist him in going about. Of the ten patients seen since the presentation of the first paper, three have died, one from pneumonia and two from cerebral hemorrhage. I was fortunately able to secure an autopsy in one of the latter cases, and was permitted to remove the posterior part of the eyeballs and the optic nerves for examination. The results of the microscopic examination were almost identical with those of the two cases previously reported. Sections made of the retina, choroid, and optic nerve showed very extensive angiosclerosis. The adventitia and media were decidedly thickened, but the main increase was in the intima, which in many places was so marked as almost to obliterate the lumen. The proliferation in the adventitia was largely granular, while the thickening in the intima was mainly due to hyalin deposit. Numerous fusiform aneurismal dilatations were found in the arteries, almost always at the point of origin of a branch; and on the distal side of these dilatations the caliber of the vessel was markedly narrowed. There were a number of hemorrhages, always close to the vessels. The nerve fibers on the papilla and in the retina were markedly varicose, and the spaces between them were filled by finely granular matter. In the retina the nerve-fiber layer was thickened by infiltration with a mass of fine granules, aggregated in heaps, with occasional distinct cells filled with the same granular contents. These masses of fine granules extended through all the layers of the retina except that of the rods and cones, most of them, however, being in the nerve-fiber layer. Sections of the optic nerves at various points as far back as the chiasm showed the same changes in the walls of the blood-vessels, and more or less marked varicosity of the nerve-fibers, and small masses of fine granules. The choroidal blood-vessels showed the same changes of general angiosclerosis. No patches of exudation were found anywhere in the chorioid, such as existed in the retina.

The following brief conclusions have been drawn from the cases presented: (1) The changes in the fundus are always bilateral, though rarely symmetrical in the two eyes. The lesions may begin simultaneously in the two eyes, but this is by no means always the case. (2) The degenerative changes in the walls of the blood-vessels, both arteries and veins, are at first very minute, and are often overlooked. They must be carefully searched for, as they begin in the intima. (3) The general angiosclerosis, and the patchy exudation in the retina, cause marked impairment of central vision, but little impairment of the peripheral vision, and the disease never ends in blindness. (4) The loss of central vision is always progressive up to a certain point. Improvement of the vision, after the retinal disease is established, cannot be expected, though in favorable cases the existing vision may be maintained. (5) Hemorrhages into the retina are rare except in the comparatively early stages of the disease. When the vessels lose their elasticity by reason of the increase in the thickness of their walls, due to the deposits, the vessels become stronger and more rigid, and hemorrhages are no longer to be feared. (6) The most marked feature in the ophthalmoscopic picture is the development of the angiosclerosis in the vessels of the retina. This condition is confirmed by the microscope, and is seen to extend to the vessels of the optic nerve and choroid. (7) Another almost equally marked symptom is the peculiar yellowish granular exudation in the retina, located by the ophthalmoscope around the posterior pole of the eye, and generally leaving the macula intact until late in the course of the disease. This exudation is shown by the microscope to be mainly in the nerve-fiber layer, though found in all the layers except that of the rods and cones. (8) The changes in the optic nerve-fibers seem to be generally intra-ocular, but have been traced occasionally for some distance back of the eyeball.

THE DOCTRINE OF THE INTERNAL SECRETORY ACTIVITY OF GLANDS IN RELATION TO THE PATHOLOGICAL ANATOMY OF SUNDRY MORBID CONDITIONS.[1]

BY J. GEORGE ADAMI, M.D.,
OF MONTREAL;
PROFESSOR OF PATHOLOGY IN MC GILL UNIVERSITY.

DIABETES, ADDISON'S AND GRAVES' DISEASE, MYXEDEMA, CRETINISM, AND ACROMEGALY.

MORBID anatomy alone can tell us singularly little concerning alterations in function. The existence of lesions recognizable to the naked eye or under the microscope may support conclusions reached by other means. It can do little more. We know from experiment that three-quarters of the liver, for example, may be removed from the healthy animal with no pronounced disturbance of the bodily functions; that whenever one-fifth or less of the pancreas is left in the dog it may be weeks before diabetes shows itself; that only when fifteen-sixteenths of the thyroid is removed may the dog succumb. In this enormous reserve of material and force may truly be said to lie the secret of the continued existence of living beings. Thus the mere fact that the greater part of an organ is found wanting by the anatomist, or replaced by tissue of another nature, is not in itself absolute evidence that what remains of the organ is functionless or incapable of meeting the needs of the organism.

Another matter which must be taken into account, one that until now has received scant attention, is the existence of vicarious activity. Because one organ is seriously diseased it does not follow that the organism as a whole exhibits disturbances commensurate with the lesions in that organ; other parts may vicariously fulfil its functions. We have the well-known example of total extirpation of so important an organ as the spleen being succeeded by continued good health. Here, presumably, the lymph-glandular tissue in general takes up the functions of the absent organ. There is the compensatory development of the parathyroids in athyrea, and further, the frequent, but not constant coexistence of atrophic disease of the thyroid and hypertrophy of the pituitary to which Boyce and Beadles have more especially called attention. Similarly and curiously we meet with frequent persistence or enlargement of the thymus when either the thyroid or the pituitary body is the seat of disease. In passing, I may suggest that vicarious activity affords a possible explanation of the not infrequent cases in which we have the eventual coexistence of more than one of the diseases under consideration. If, for example, the thyroid be the seat of atrophic disease the compensatory hypertrophy and over-action of the pituitary may lead to eventual affection of that organ.

Yet another consideration, seriously weighing upon the morbid anatomist, is that two opposite processes may produce a similar symptomatology; one that he can recognize, another that he cannot. If the glands afford an internal secretion entering the lymph and so eventually circulating through the system, we know that the ultimate use of the secretion must be to effect a chemical transformation of some substance in some other part or parts of the system. There are thus four possible conditions: (1) Production of an insufficient amount of internal secretion of any gland in consequence of disease of that gland, and (2) the assimilation or production of an excess of that substance which normally is acted upon and transformed by the internal secretion in question. In both cases there will be a heaping up of the substance in the system; in both cases there may be the same train of symptoms. In the one case the gland or glands may show the clearest signs of disease; in the other they may appear normal. The morbid anatomist may in time discover collateral disturbances distinguishing these two states; at present he cannot adequately. In one case of diabetes he finds the pancreas unaffected; in the next it is extensively diseased. Unaided by experimental pathology, he is quite incapable of determining the important *rôle* played by this organ in regulating the sugar supply of the organism and in the production of diabetes. Similarly there may be an accumulation of the in-

[1] Abstract of a contribution to the discussion upon "Internal Secretions," at the Fourth Triennial Congress of American Physicians and Surgeons, Washington, D. C., May 5, 1897.

internal secretion, either due to (3) hypertrophy of a gland, or (4) not associated with recognizable glandular change.

It would seem that we have to deal with:

CHANGES ASSOCIATED WITH SYMPTOMS OF DISEASE.

I. Relative glandular inadequacy. Excess of substance acted upon by the internal secretion of a gland, without due compensation.

1. Altered condition of gland leading to diminished activity and diminished internal secretion.

2. No disease or alteration of gland but excessive production or assimilation of the substance acted upon by the internal secretion.

II. Relative glandular over-activity. Excess of internal secretion.

1. Altered condition of gland leading to increased activity and increased pouring out of internal secretion.

2. No disease or alteration of gland, but diminished production or assimilation of the substance acted upon by the internal secretion of that gland.

CHANGES UNACCOMPANIED BY SYMPTOMS OF DISEASE.

III. Compensation. Lesions of gland or altered systemic condition unaccompanied by symptoms.

1. Altered condition of gland leading to (*a*) increase or (*b*) diminution of internal secretion, with due compensation.

2. (*a*) Increased or (*b*) diminished production after assimilation of substance acted upon by internal secretions, with due compensation.

Let me here emphasize the fact that I do not pretend that this table includes every possible condition leading to local or general disturbance of these glands affording an internal secretion, and leading to the symptoms most often associated with disease of these glands. For example, we know from experiments with phloridzin that glycosuria may, among other things, be the result, not so much of increased production of sugar as of increased removal of this body through the kidneys. Such cases are not embraced in this table. Again, what I may term compound cases, as, for instance, of glandular inadequacy, in part from disease, in part from increased production of the substance acted upon by the secretions, are presented only by implication. All I urge is, that this table, conforming with what experiment has shown may occur, may very possibly be utilized to explain the apparently contradictory revelations of the *post-mortem* room.

THE PANCREAS AND DIABETES.

Much more than a century has passed since attention was first called to the pronounced changes to be seen in the pancreas in some cases of diabetes. We all know that not until 1889, when Von Mering and Minkowski in Germany, and de Dominicis in Italy, published the results of their researches did the belief in the existence of a pancreatic diabetes begin to become generalized, but even at the present moment the fact that two cases, closely resembling each other clinically, may, *post-mortem*, show, the one, extensive pancreatic disturbance, the other, an apparently healthy pancreas, will create great confusion.

We have at least three careful studies upon this subject, those of Hansemann, Williamson, and Dieckhoff, and all demonstrating that three conditions may be distinguished: (1) extensive pancreatic disease with associated diabetes; (2) extensive pancreatic disease without diabetes; (3) diabetes unassociated with recognizable pancreatic disease. Hansemann, from a careful investigation of the records of the Pathological Institute and the Augusta Hospital at Berlin, found that the first condition (of pancreatic disease with diabetes) is more common than the two others combined. It may be that in Berlin the consumption of much beer predisposes to the pancreatic form of the disease; it may be that the material upon which Hansemann worked was imperfect to this extent, that full care was not taken to distinguish between extensive and extreme destruction of the pancreatic tissue; but it will, I think, be the experience here, as it was of Williamson in England, and Dieckhoff in Rostock, that advanced pancreatic disease, associated and unassociated with diabetes, are to be encountered the one but little more frequently than the other.

This much, however, stands out very prominently, that where in diabetes the pancreas is found affected, the morbid process within the gland is some one or other form of atrophy and destruction of the gland substance. Most commonly it is a form of periacinous fibrosis, originating, it would seem, secondarily to arteriosclerosis, in which, with thickening of the arterial walls, there is malnutrition of the gland cells, atrophy, and, what I have elsewhere termed, replacement fibrosis. Other forms of atrophy and fibrosis have not infrequently been observed—simple atrophy, congenital syphilitic fibrosis, obstruction of the ducts with calculi, dilation of the ducts and atrophy of the gland tissue, and scirrhous cancer of the pancreas; and I have found recorded five cases of necrosis, or hemorrhagic necrosis (two by Fitz and a third, a case under Drs. Bell and Finley, in my own experience at the Montreal General Hospital).

There can, therefore, be no question that the pancreatic lesions found in some cases of diabetes are such that there must be a marked diminution in the secretory activity of the gland. To this extent, in this one class of cases, the results of autopsies are clearly in accord with the results of experiments. We have here examples of relative glandular inadequacy, brought about by altered conditions of the pancreas leading to diminution of internal secretion.

Examples of diabetes unassociated with disease of the pancreas are so well known that I need but refer to them. While such are difficult to explain, from purely anatomic considerations, the fact that they are found, and found relatively frequently, is, in itself, an evidence that glycosuria is of at least a two-fold origin. That they are found is in conformity with the results of experiments—experiments which, on the whole, must be regarded as proving that there can be heaping up of sugar in the organism beyond the transforming power of the pancreatic internal secretion, or otherwise an incomplete burning up of the sugar. If this heaping up be in general due to increased glycogenesis, increased production of sugar, we should expect to find some evidence of increased activity of some glycogenetic organ; and here the recent researches of Glénard and Triboulet tend to show that this may be the case. Contrary to the older and generally accepted teaching, Glénard finds that, clinically, in over sixty per cent. of diabetics there is evidence of some hepatic enlargement. Anatomically, he finds that three conditions may be recognized, each possibly a stage in one morbid process, namely, hyperemia, general cellular hypertrophy (hyperplasia), and hypertrophy with cirrhosis (hypertrophic cirrhosis). Thus, while I will not say that anatomic considerations prove the existence of my second subgroup in this connection, I must point out that the existence of this class of cases of diabetes, without adequate recognizable pancreatic disturbance, is best explained on the supposition that there may be excessive production or assimilation of sugar, with accompanying relative pancreatic inadequacy.

There is yet a third group of cases to be considered—that of extensive atrophic disease of the pancreas without diabetes. Here we have to proceed cautiously in our reasoning. As I have already indicated, Sandmeyer has found that if only one-fifth to one-ninth of the organ be left in the dog, it may be months before sugar appears in appreciable quantities in the urine. Vaughan Harley gives an even smaller amount, namely, one-fifteenth; but evidently he refers not to the eventual development of diabetes, but to its onset within a few hours. We can thus state that so long as from one-ninth to one-fifteenth of the glandular tissue of the organ is functional, for so long glycosuria need not manifest itself in the dog. There is no valid reason why we should not apply these facts to the human being. Hence, so long as a very small proportion of fairly healthy gland tissue is left, we have a satisfactory explanation of why diabetes should not show itself, even though the major portion of the pancreas exhibits fibroid and atrophic or neoplastic changes. There are, however, aspects of the subject not capable of so simple an explanation. Again, Hansemann has called attention to cases of complete replacement of the normal pancreas by a diffuse cancerous infiltration. He seeks to explain these by the hypothesis that the cells of a primary new growth of a ductless gland may continue to furnish an internal secretion. This may or may not be the case. A more simple explanation of these and other examples of complete, or almost complete, destruction of the pancreatic glandular tissue is that of compensation, whether by vicarious function of Brunner's and other glands (the duodenal glands have frequently been found enlarged) or by diminished assimilation or production of sugar.

THE SUPRARENAL BODIES AND ADDISON'S DISEASE.

We meet with an identical series of cases in connection with another organ in which, experimentally, the existence of an internal secretion has been fully demonstrated. We may have (1) Addison's disease associated with disease of the suprarenal bodies; (2) Addison's disease with intact suprarenals; and (3) extensive, if not complete, destruction of the suprarenal bodies without the symptoms of Addison's disease.

Here, as with the pancreas in diabetes, the affection of the gland in Addison's disease is some form of atrophy or destruction of the specific gland tissue. Most frequently, I need scarcely say, the change is tuberculous and necrobiotic, resulting in the disappearance of the gland tissue, and its replacement by caseous material. But cases are on record of simple atrophy, hemorrhagic necrosis, and malignant growth of the bodies associated with or leading to all the symptoms of Addison's disease. In the vast majority of cases both glands are affected, but cases are on record (I have come across one such) where only one of the bodies has been the seat of recognizable disease. Of the three conditions above mentioned the most frequent found is the association of the disease with complete, or almost complete, destruction of the gland. So frequent is the association that the attempts to explain away the other two rare states of Addison's disease with intact suprarenal bodies and suprarenal disease without the Addisonian symptoms have been almost painful in their ingenuity. Yet undoubtedly well-authenticated cases are on record of both of these conditions.

We have in this connection singularly full statistical collections of cases. That of Lewin is well known; he collected accounts of 285 cases, of which 211 showed caseous lesions of the suprarenals (seventy-four per cent.). Gilman Thompson found an even greater proportion of either primary or secondary tuberculosis (eighty per cent.). In the remaining twenty per cent. there were either other forms of atrophic disease or absence of recognizable disturbance.

The existence of cases of Addison's disease without obvious disease of the suprarenals is generally acknowledged. Lewin found that as many as twelve per cent. of his cases were of this type. The explanation generally given is that in these there had been alterations in the neighboring semilunar ganglia and abdominal sympathetic. Certainly, disturbance of the nervous system, and especially of the sympathetic, does lead to pigmentation of the skin. We see this in cases of hysteria, and again in Graves' disease, in which, from whatever cause, we have most marked nervous changes; but I must confess that I feel some little impatience toward the upholders of this semilunar ganglion theory of Addison's disease, for scarce two of them describe the same order of lesions. Most of the changes described would appear to be quite common in the adult dying from other causes; thus Hale White found that, examining thirty-three semilunar ganglia removed indiscriminately, if we leave out of account three perfectly normal taken from young children, twenty-four, or eighty per cent., of the remainder exhibited more or less extensive degenerative changes, with frequent presence of granular masses of pigment.

Under the circumstances, therefore, I see no valid reason why cases in which the bodies are found apparently unaffected may not, in the light of our present knowledge, be most satisfactorily classed as possible examples of relative glandular inadequacy of the second order. This suggestion may to some appear revolutionary; but let me reiterate my main argument: We acknowledge that glands like the suprarenals produce an internal secretion; we must inevitably admit that the function of such secretion is to affect a chemic transformation of some substance or substances distributed in other parts of the body. We must admit that when, for example, the suprarenal bodies are diseased, or removed, some, at least, of the symptoms that follow are due to the absence of the internal secretion, or, in other words, are due to the accumulation in the system of the substance or substances acted upon by the internal secretion. The same symptoms must be produced whatever the cause of the accumulation of the substance or substances, whether by diminution of the internal secretion or by excessive production or assimilation of the aforesaid substance or substances. When, therefore, a morbid condition, such as diabetes or Addison's disease, which may be caused by destruction of a gland, is found to exist without recognizable disease of that gland, a very possible explanation of the condition is what I have termed relative glandular inadequacy due to excessive production or assimilation of the substance acted upon by the internal secretion. I would but ask you clearly to picture this: That in diabetes and Addison's disease it is not the internal secretion that causes the symptoms, but if experimental data are to be trusted, the lack of the same—and that this lack may be absolute or relative.

A few words only are necessary concerning affections of the suprarenal bodies without symptoms of Addison's disease. If bronzing be required as the one essential symptom, then cases of tuberculous disease of the suprarenal without "Addison's" are fairly frequent. Addison himself noted this condition. We must, however, it seems to me, acknowledge, with Chvostek and numerous earlier writers, that bronzing is but one of a group of symptoms, even though we are not prepared to accept Bedford Fenwick's suggestion that bronzing is especially connected with disease of the cortical layer. Leaving this category out of consideration, cases of extensive atrophic or neoplastic disturbance of both suprarenals without Addison's disease are few in number—far fewer than the cases of extensive pancreatic disease without diabetes; and in general the descriptions given are not sufficiently exact to be relied upon. Nevertheless, they exist. Greenhow apparently met with a case of almost complete atrophy without symptoms, and, in 1050 autopsies, upon subjects dying from diseases other than Addison's. Rolleston met with an example of caseation of the right and atrophy of the left suprarenal and with three cases (under the age of forty-five) in which both were peculiarly small. All these were without symptoms during life. There are more frequent examples recorded of cancerous growth destroying both bodies without noticeable symptoms. There is a possibility that the new growth here was so rapid and so recent that symptoms had not time to develop. In the atrophic and tuberculous cases it is not so easy to accept this explanation. Therefore, I am inclined to believe that compensation may occasionally manifest itself in man as it does occasionally in animals which have suffered complete ablation of both organs.

THE THYROID GLAND AND MYXEDEMA.

From an anatomic point of view there is little for me to say in elucidation of the pathology of myxedema beyond the one all-important statement that, with very rare exceptions, there is discoverable a well-marked atrophy of the thyroid. About this all pathologists are agreed. In the majority of cases the atrophy is peculiarly extensive, the specific cells of the gland being replaced by fibrous tissue; in some it is not so far advanced and areas may be found, not merely of degenerated remains of the vesicular epithelium, but of vesicles which by the superabundant proliferation of their epithelium would seem to be undergoing a compensatory hypertrophy. Yet where these are present they are localized and few in number; the main mass of the organ shows atrophy. A few cases only are on record, like that of Gulliver, where there has been a cancerous metamorphosis or replacement of the parenchyma. That in these cases the myxedema is associated with diminished internal secretion of the gland is, I need scarcely say, substantiated by the good effects of treatment by thyroid extract or thyroid feeding.

It must next be asked whether myxedema can show itself with apparently intact thyroid, *i. e.*, whether there are any cases which may possibly be explained by excess of the substance or substances acted upon by the internal secretion of the gland. The literature is peculiarly silent upon this point. I can find no example of autopsies upon cases diagnosed clinically as myxedema in which the gland was found normal, or but little affected. I can only recall an autopsy upon a patient of Dr. J. Stewart at the Royal Victoria Hospital, in which I found a large cancerous tumor of the pituitary. Here there had been a myxedematous swelling of the hands, and of other regions to less extent, without bony overgrowth, and no change was found in the thyroid. The condition, however, was not sufficiently advanced to deter Dr. Stewart from diagnosing tumor of the hypophysis. A somewhat parallel case (of apparent atrophy of the pituitary), in which the symptoms of myxedema were more marked, is recorded by Codd, but the anatomic details are given very briefly. Similarly we possess no exact records of atrophic disease of the glands unassociated with myxedema. I can only point out that it is not uncommon in the aged who show no signs that can properly be regarded as myxedematous—unless senility itself be regarded as such—to find a condition of very extensive chronic interstitial thyroiditis (as it may be termed) with arteriosclerosis, calcification, and hyalin changes, with retrograde or pseudo-embryonic type of vesicles. I have come across more than one case of this nature. There can be no doubt that here the secretory activity of the gland tissue must be very greatly reduced. If, however, we turn to cases in which by surgical means the equivalent of complete atrophy, namely, complete thyroidectomy, has been attained, we then possess abundant evidence that the thyroid proper may be absent without myxedema necessarily intervening, and almost as abundant evidence from the more recent researches that the absence of symptoms is connected with vicarious activity on the part of other organs, and especially of the parathyroids. These may be regarded either as true accessory thyroid tissue, or as distinct organs, according to the point of view of the individual. Certainly when the thyroid is functional they do not acquire the full characters of thyroid tissue, but similarly there are often within the healthy organ scattered areas of embryonal tissue. This can be said with precision: that they are independent masses of tissue, apparently most closely related to the thyroid, which are at times capable of development to, or toward, the adult type of the gland, and of assuming vicarious functions. In like manner the pituitary body can at times undergo very definite compensatory enlargement.

An interesting point in this connection, to which attention has been drawn by Rogowitsch, is that the rabbit, from which the thyroid can be removed with impunity, has a pituitary body relatively five times as large as that of the dog, in which ablation of the thyroid leads rapidly to symptoms of acute athyrea; or, more correctly, the relationship of thyroid to pituitary is 3 to 1 in the former, 15 to 1 in the latter animal.

On the whole, therefore, anatomic data in connection with myxedema and cachexia thyreopriva support and are capable of explanation by this doctrine that where glands afford an internal secretion, the development or non-development of symptoms of disease depends primarily upon the relative amount of internal secretion produced and of the substance or substances acted upon by the same.

CRETINISM.

Cretinism presents a far more complicated histologic picture—so complicated that Bircher argues with very considerable force that "cretinic degeneration, as also dwarfism and chondrodystrophia fetalis hypoplastica have no etiologic connection with the functions of the thyroid." Bircher, however, fails to recognize that if we accept the existence of an internal secretion, we must also admit the presence of substances upon which it acts, and he cannot see that widely contrasted anatomic conditions may lead to the same train of symptoms. We must, I think, abide by the experimental and clinical evidence that removal of the thyroid in the young leads to a condition undistinguishable from cretinism. This being so, we find that in some few cases of typical cretinism the thyroid is completely absent, in a large number it is small, in a yet larger number, according to Von Eiselberg and Kocher, there is a goitrous condition present, while, according to Bircher, the goiters may be of all possible forms, from simple hyperplastic through soft (parenchymatous) and cystic to fibroid. The only point clearly to be made out from Bircher's very destructive criticism is that while in several cases the thyroid has been found of normal size, apparently no case exists in which by microscopic observation it has been found of normal structure.

EXOPHTHALMIC GOITER.

I will now briefly refer to the condition which presents a series of symptoms so remarkably contrasted with myxedema—which also anatomically presents an equal contrast. There is to be found in exophthalmic goiter, as Greenfield has shown, and as is now generally accepted, a characteristic hyperplasia of the thyroid parenchyma, complicated, it may be, in later stages, by increased fibrosis. The one question of immediate concern here, is whether from this we can safely deduce that there is accompanying increased internal secretion. As I have already hinted, I do not think that from anatomic considerations alone we can safely make this deduction. There is, however, an important fact in favor of such deductions, namely, the strong likeness between the primary glandular changes in Graves' disease and those described by Halsted and others as occurring in the compensatory hyperplasia of the thyroid after removal of large portions of the gland; and if, together with the anatomic changes, we consider the favorable effects which so often follow removal, destruction, or diminution in the blood supply of portions of the hypertrophied gland in this disease—of operations which must lessen the internal secretion—it is difficult to arrive at any other conclusion than that in exophthalmic goiter there is increased internal secretion, and that this plays a singularly important part in the development of the symptoms. Whether this be primary or secondary to lesions of the central nervous system—of the restiform bodies, for example, our present anatomic data are insufficient to decide—as again they are incapable of deciding whether the increased secretion is altered or unaltered in quality. I may here note that, as Joffroy and Achard have indicated, the symptoms of parenchymatous and adenomatous goiter are at times curiously allied to those of exophthalmic goiter. Indeed, together with Vanderweld and Le Bœuf, they hold, I think, without due cause, that there is nothing anatomic to distinguish the one condition from the other. That the one condition may lead to the other is a matter of clinical experience. As Dr. Shepherd has pointed out to me, extirpation of the goitrous nodules or cysts leads to the almost immediate amelioration of the symptoms.

The development of exophthalmic goiter without hyperplastic alteration of the thyroid is a matter concerning which there is little anatomic evidence. I find one case recorded by Joffroy and Achard in which the gland was of normal size and, while not normal histologically, presenting nevertheless a series of changes wholly distinct from Greenfield's classic description. The vesicles, instead of being small and corrugated, were enormously distended; instead of absence, there was abundance of colloid material; in place of a columnar and proliferating epithelium, the lining cells were flattened. Not a few believe in the existence of Graves' disease without goiter. Among recent writers Buschan especially holds this view, but, save in the above case, I cannot find anatomic substantiation for the opinion. Clinically, Graves' disease without enlarged thyroid has very frequently been noted; in some cases enlargement supervenes, in others it does not, but there may well be increased activity of the gland without marked enlargement. All that can be said at present from this evidence is that apparently the condition does occur. So also evidence as to the occurrence of marked hyperplasia and presumably increased secretion without symptoms is not so full and precise as could be wished. I can only point out that if adenomatous nodules in the thyroid produce any internal secretion then, while many cases of adenomatous goiter show a train of symptoms somewhat allied to exophthalmic goiter, and while a few cases pass on to undoubted Graves' disease, many, on the contrary, appear to last for years without symptoms. And in autopsies upon those dying from diseases other than exophthalmic goiter, we find a wide variation in the condition of the thyroid, from atrophy on the one hand to a condition not far removed from what Greenfield and others describe in association with exophthalmic goiter.

THE PITUITARY BODY AND ACROMEGALY.

Finally, some few words must be said concerning that strange collection of symptoms and anatomic changes to which Marie has given the name of acromegaly. Yearly it has become more clearly recognized that the term indicates a definite disease, although there is a liability toward confusion with gigantism on the one hand, and on the other with the remarkable overgrowth of bone in certain cases of chronic disease (mainly of the lung) which again Marie was the first to group together under the title

—voluminous, and in other respects unsatisfactory—of hypertrophic pulmonary osteoarthropathy.

Here again the remarkable trio of conditions forces itself upon our notice; there may be acromegaly with disease of the pituitary, acromegaly with apparently unaffected pituitary and extensive disease of the pituitary without acromegaly. Where there is acromegaly, in by far the greater number of cases the glandular portion of the body is diseased. It is true that the condition is rare. Between 1890 and the present time less than thirty affected subjects have undergone *post-mortem* examinations. Out of 24 necropsies upon cases stated to be acromegaly, Tamburini, the latest collector, finds that in 17 (or over 70 per cent.) the pituitary has been found diseased. The remaining 7 are subjected by Tamburini to severe criticism, with the result that he rejects 2 on the ground that the condition had only been recognized clinically for a few months, and no microscopic examination had been made. He presumes that the time had not been sufficient for the development of naked eye changes. Three other cases he holds to have been osteoarthropathy. There remain two which he could not definitely reject and consequently classified as doubtful. So far as I can follow Tamburini, he is strongly of the opinion that morbid changes in the hypophysis cerebri are essential to acromegaly. The majority of observers do not accept this extreme view, and with them I am inclined to believe that here, as certainly obtains in diabetes and Addison's disease, there may be typical symptoms without recognizable involvement of the pituitary.

But granting this much, that in the majority of instances the gland is diseased, it is difficult to advance much further, for there is a curious discord concerning the exact nature of the alterations in the pituitary body. In about one-half of the cases, hypertrophy of the organ is described. Stroebe, Tamburini, Boltz, and others of later date conclude that the change is adenomatous; Marino, Dallemagne, and Gauthier describe a peculiar cystic degeneration, and Boyce and Beadles a cystadenoma, while in another of Dallemagne's cases and in Wolf's there was clearly sarcoma, and in Bury's a "glioma." What are we to conclude? Is acromegaly accompanied by an increased pouring out of internal secretion, or the reverse? Mere hypertrophy and possibly adenomatous overgrowth might lead to increase, but surely degenerative changes and sarcoma can have no such effect.

It is difficult to reason by analogy, and if we attempt this and seek to base any argument upon what occurs in disease of the gland, which anatomically is most closely related to the pituitary—namely, the thyroid—we are led rather to the conclusion that acromegaly must be due to arrest of function of the former. That is to say, there is a certain correspondence between the changes occurring in the connective tissues, in myxedema, and those affecting the bone, and to some extent the subcutaneous connective tissues in acromegaly.

On the other hand, the pituitary is nearly always found enlarged and hypertrophied in general gigantism, as distinguished from this localized acromegalic gigantism. It is difficult to reconcile such general gigantism with diminished activity on the part of the enlarged hypophysis, while again the contrast may be pointed out between gigantism and cretinic dwarfism. Tamburini, and independently Massolongo, have attempted to coordinate the contradictory anatomic discoveries by suggesting that two stages of the disease may be recognized, a first in which the hypophysis undergoes hypertrophy, and is in overaction, which may give place to a second in which the hypertrophied tissue either undergoes atrophy or adenomatous or sarcomatous change. The suggestion is seductive, but for the present must be regarded merely as a suggestion.

Briefly, therefore, our knowledge in this connection is miserably inadequate, and experiments have so far been without result. We cannot say whether in acromegaly there is increased or diminished internal secretion. While the change in the pituitary appears often to be primary, we cannot with certainty lay down that this is the case. It has only to be added that if we admit that lesions of the pituitary are associated with acromegaly, we must also admit that compensation can occur, for there is considerably over a score of cases on record of hypertrophy, adenoma and cystadenoma of the organ, all of considerable size and presumably of long duration, which had developed without signs of the disease in question.

CLASSIFICATION OF ACUTE PERITONITIS.[1]

By N. SENN, M.D.,
OF CHICAGO;
PROFESSOR OF PRACTICE OF SURGERY AND CLINICAL SURGERY
IN RUSH MEDICAL COLLEGE; PROFESSOR OF SURGERY IN
THE CHICAGO POLYCLINIC; ATTENDING SURGEON
TO THE PRESBYTERIAN HOSPITAL, ETC.

Acute inflammation of the peritoneum is produced by so many different causes and assumes such varied clinical aspects that it is extremely difficult to formulate a satisfactory classification of the condition. A discussion of its etiology, differential diagnosis, prognosis, and treatment, except upon the basis of a clear and comprehensive classification, is fruitless and misleading, and usually results in the deduction of erroneous and often dangerous conclusions. The classification should include the anatomy, pathology, and etiology of the disease to be of value in rendering a correct diagnosis and a reliable prognosis, and to enable the physician and surgeon to advise and apply effective therapeutic measures.

---

[1] Abstract of a paper read at the Fourth Triennial Congress of American Physicians and Surgeons, Washington, D. C., May 5, 1897.

I. ANATOMIC CLASSIFICATION.

An accurate anatomic diagnosis is necessary for the purpose of locating the inflammatory process correctly or to trace the connection between it and the organ primarily the seat of infection. During the beginning of the attack and in cases of localized peritonitis, the inflammation can usually be located without much difficulty, while the reverse is often the case after the disease has become diffuse. The inflammation may commence and spread from either surface of the serous membrane, visceral and parietal.

a. Ectoperitonitis.—An inflammation of the attached side of the peritoneum is called ectoperitonitis. As compared with inflammation of the serous surface, this inflammation of the subendothelial vascular connective tissue is characterized clinically and pathologically by intrinsic tendencies to limitation of the inflammatory process. In infected wounds of any part of the abdominal wall in which the peritoneum is exposed but not perforated, the primary ectoperitonitis is occasionally followed by the extension of the infection to the serous surface through the lymphatics, or by the direct extention of the infective process through the tissues until it reaches the endothelial lining. Peritonitis of a visceral origin is always preceded by ectoperitonitis, whether the infection reaches the peritoneal cavity through a perforation or by aggressive extension of the infection from a primary focus through the tissues until it reaches the free peritoneal surface.

b. Endoperitonitis.—What is usually spoken of and described as peritonitis is an inflammation of the serous surface of the peritoneum, which, anatomically speaking, is an endoperitonitis.

c. Parietal Peritonitis.—Inflammation of the serous lining of the peritoneal cavity is called parietal peritonitis. It may occur as a primary affection in penetrating wounds of the abdomen, but more frequently is met with as a secondary disease in consequence of the extension of an infection from one of the abdominal or pelvic viscera, or perforation into the peritoneal cavity of a visceral ulcer or a subserous or visceral abscess.

d. Visceral Peritonitis.—Inflammation of the peritoneal investment of any of the abdominal or pelvic organs is known as visceral peritonitis. The inflammatory process is seldom limited to a single organ, as during the course of the disease adjacent organs or the parietal peritoneum will surely become involved. In diffuse peritonitis the whole peritoneal sac and the serous covering of all the abdominal organs is affected. The nomenclature of visceral peritonitis is a lengthy one, as it includes all of the abdominal and pelvic organs from which, when the seat of a suppurative inflammation, may become the primary starting point of an attack of localized or diffuse peritonitis.

e. Pelvic Peritonitis.—Inflammation limited to the peritoneal lining of the pelvis and its contents is known clinically and anatomically as pelvic peritonitis. It is an affection almost entirely limited to the female sex, and in the majority of cases is caused by extension of gonorrheal infection from the Fallopian tubes, or a mild form of pyogenic infection from the uterus, its adnexa, or the connective tissue of the parametrium.

f. Diaphragmatic Peritonitis.—Inflammation of the under surface of the diaphragm is described as diaphragmatic peritonitis, and when it assumes a suppurative type and remains limited, leads to the formation of a subdiaphragmatic abscess. This acute localized form of peritonitis is usually secondary to suppurative affections of the liver and gall-bladder, and perforating ulcers of the stomach and duodenum.

2. ETIOLOGIC CLASSIFICATION.

The classification of peritonitis upon an etiologic basis is of the greatest importance and practical value. The nature of the exciting cause frequently determines the anatomic and pathologic varieties. It likewise has a strong bearing upon the prognosis, and often furnishes positive indications as to the methods of treatment which should be adopted. Peritonitis, like every other inflammatory affection, is always the result of infection with pathogenic microbes, usually of the pyogenic variety. The etiology must consider the different avenues through which the microbes find their way into the peritoneal cavity.

a. Traumatic Peritonitis.—Primary peritonitis has usually a traumatic origin; that is, the injury establishes a communication between the peritoneal cavity and the surface of the body or some of the hollow abdominal or pelvic organs, through which pyogenic bacteria enter in sufficient quantity and adequate virulence to cause an acute inflammation.

b. Idiopathic Peritonitis.—The occurrence of peritonitis without an antecedent injury or suppurative lesion is doubted by many. It is too early to deny *in toto* the existence of so-called idiopathic peritonitis, but future bacteriologic examinations of the inflammatory product will no doubt reveal a microbic cause in all such cases. As an isolated affection, peritonitis is found most frequently in females during or soon after menstruation. It is probable that the pyogenic bacteria multiply in the blood which accumulates in the uterus and reach the peritoneal cavity through the Fallopian tubes. It is said to have occurred in consequence of exposure to cold, and is then known as rheumatic peritonitis. Occasionally it has been observed as one of the remote manifestations of Bright's disease, pyemia, and the acute eruptive fevers.

c. Perforative Peritonitis.—Perforation of an ulcer of any part of the gastro-intestinal canal, or of an abscess of any of the abdominal or pelvic organs, or of the abdominal wall into the peritoneal cavity, is by far the most frequent cause of acute peritonitis. Two important and frequent causes are appendicitis and suppurative salpingitis.

d. Metastatic Peritonitis.—This form of peritonitis occurs, like other metastatic affections, in connection with suppurative or infectious processes not connected with the peritoneum. In very rare cases it develops in the course of many of the acute infectious diseases, as scarlatina, smallpox, erysipelas, rubeola, and even varicella. It also occurs frequently in the course of septicemia and pyemia.

e. Puerperal Peritonitis.—Peritonitis occurring in connection with septic diseases of the puerperal uterus has for a long time been known as puerperal peritonitis. The infection may extend from the endometrium through the Fallopian tubes, or it may follow the lymph channels or the thrombosed infected uterine veins. Infection through the lymphatics usually results in rapidly fatal diffuse septic peritonitis, while in thrombophlebitis there is a greater tendency to localization, unless the thrombi disintegrate and cause embolism and pyemia.

3. PATHOLOGIC CLASSIFICATION.

The pathologic conditions which characterize the different varieties of peritonitis necessarily must be considered in classifying this disease. The pathologic classification is based almost entirely upon the gross and microscopic appearances of the inflammatory exudation and transudation.

a. Diffuse Septic Peritonitis.—Every acute peritonitis is septic in so far that phlogistic substances reach the general circulation from the inflammatory lesion, and in that frequently the inflammation terminates in suppuration; but the term "septic peritonitis" should be limited to those cases of diffuse septic peritonitis in which, as a rule, death occurs in a few days, and before any gross pathologic conditions have had time to form. It is a disease that is almost uniformly fatal, with or without operative treatment, the patients dying from the effects of progressive sepsis. The claim of operators to have cured such cases by laparotomy must be accepted with a good deal of allowance. The microbes which produce this form of peritonitis are those which follow the lymph spaces and are rapidly diffused not only over the entire peritoneal surface, parietal and visceral, but also through the subserous lymphatic channels. The disease is observed most frequently after perforation into the free peritoneal cavity of an abscess containing septic pus; rupture, or perforation of any of the abdominal or pelvic viscera containing septic material; gunshot or stab wounds of the abdomen with visceral injury of the gastro-intestinal canal; and occasionally as the result of infection during a laparotomy. The gravest form of puerperal fever is a diffuse septic peritonitis. The subjects of this variety of peritonitis die so soon after the beginning of the disease that at the autopsy no gross tissue changes are discovered. Besides a slightly increased vascularity, nothing is found to indicate the existence of peritonitis. The septic material, formed in large quantities and of great virulence, is rapidly absorbed by the stomata of the under surface of the diaphragm discovered and described by Von Recklinghausen.

b. Suppurative Peritonitis.—Suppurative peritonitis, that is, an inflammation of the peritoneum which results in the formation of pus, is always more or less circumscribed. This form of peritonitis is the most frequent, and is generally associated with more or less fibrinoplastic exudation. The pus is either serous or seropurulent, or may reach the consistence of cream, when it usually is of a yellow color. The accumulation of pus may be so large that upon opening the abdominal cavity it may appear as though the entire peritoneal cavity and all the organs contained within are implicated, but a careful examination will almost always reveal the fact that a large part of the peritoneal cavity and many of the organs were shut out from the inflammatory process by plastic adhesions. Suppurative peritonitis must therefore be regarded from a practical standpoint as a circumscribed inflammation. The appearance and character of the pus are often greatly modified by the admixture of an extravasation accompanying the perforative lesion which produced the peritonitis. If the pus is thin (serous) we speak of *seropurulent peritonitis.* It is a serous peritonitis with the formation of pus in sufficient quantity to render the serum more or less turbid. This subvariety of suppurative peritonitis is without exception in combination with fibrinous exudations, which tend to limit the extension of the infective process. Sedimentation of the solid constituents takes place, so that the fluid contains more of the solid constituents in the most dependent portion of the affected district.

c. Serous Peritonitis.—Independently of malignant and tubercular disease of the peritoneum, circumscribed hydrops of the peritoneal cavity is caused by a very mild form of peritonitis, the pus microbes present not being sufficient in quantity to produce pus. Patients usually recover rapidly from this form of peritonitis. The slight alterations of the peritoneum produced by the inflammatory process do not interfere with the transudation of serum, and resorption is effected as soon as the inflammation subsides and the normal absorptive function of the peritoneum is restored. Serous peritonitis is usually more or less complicated by fibrinous peritonitis, as fragments of fibrin are often found suspended in the blood. The serum is generally somewhat turbid, not transparent, and grayish-yellow or reddish in color. As long as the fluid is limited in quantity, it gravitates toward the most dependent parts of the abdominal cavity, in the small pelvis; when more copious, it reaches the upper portions of the peritoneal cavity and first seeks the depression on each side of the spinal column.

d. Fibrinoplastic Peritonitis.—The inflammation results in a plastic exudation with little or no effusion. The character of the exudate depends on the intensity and quality of the bacterial cause. The exudation is often so copious that it has been mistaken for malignant disease. The symptoms are marked cachexia, ascites, uncontrollable diarrhea, and apparent tumor deep in the abdomen. The exudation in the course of time contracts, and results in strong bands of adhesion, which frequently flex and distort the organs to which they are attached, which has given rise to another term—*peritonitis deformans.*

4. BACTERIOLOGIC CLASSIFICATION.

As the essential cause of peritonitis is always the presence and action of pathogenic microbes and their toxins upon the peritoneum, and as the character of the inflammatory process is largely influenced by the kind of microbes which produced the infection, a bacteriologic classification is of the greatest scientific and practical importance. All pus microbes present in sufficient quantity and virulence in the peritoneal cavity can produce peritonitis.

a. Streptococcus Infection.—The streptococcus pyogenes is the microbe which is most frequently found in the tissues in cases of septic peritonitis. The infection spreads so rapidly over the peritoneal surface and through the subserous lymphatics that death, as a rule, occurs from septic intoxication before a sufficient length of time has elapsed for any gross pathologic lesions to form. Absence of fibrinous exudate and effusion are the most striking negative findings at operations and necropsies. Streptococcus infection is the immediate cause of the most fatal form of puerperal peritonitis. After the peritoneum has once been infected, rapid diffusion takes place, and finally the diaphragm and pleuræ are implicated in the same process, and the patient dies from the effects of progressive sepsis.

b. Staphylococcus Infection.—In peritonitis caused by staphylococcus infection the intrinsic tendency to localization of the disease is more marked; the inflammation results more often in circumscribed suppuration and limitation of the infective process by copious fibrinoplastic exudations. As a rule, the inflammation terminates in the formation of thick, cream-colored pus. Different forms of staphylococci are often seen in the same inflammatory product.

c. Pneumococcus Infection.—It is now well known that pneumonia is produced by different microbes, but the diplococcus is found in about eighty per cent. of all cases. It is this microbe which occasionally is found as the bacteriologic cause of acute suppurative peritonitis. Weichselbaum has found the diplococcus of pneumonia unaccompanied by any other micro-organism in three cases of peritonitis. In one case the peritonitis and acute pneumonia occurred simultaneously; in the other, double pleuritis followed the peritonitis, but in the last case the peritonitis was undoubtedly primary, and in the absence of any other microbes in the inflammatory product must have been caused solely by the diplococcus of pneumonia.

d. Bacillus Coli Commune Infection.—The bacillus coli commune, a microbe that constantly infests the intestinal canal, is in a fair percentage of cases the bacteriologic cause of acute peritonitis. This microbe possesses pyogenic properties, and in intestinal paresis and perforations escapes into the peritoneal cavity, and usually produces a pathologically mixed form of peritonitis—that is, suppurative and fibrinoplastic peritonitis.

e. Gonococcus Infection.—In the peritoneal cavity the gonococcus produces a plastic peritonitis, and sometimes localized suppuration. Salpingoperitonitis and the more diffuse pelvic peritonitis is most frequently caused by gonococcus infection.

f. Tubercular Infection.—The rapid diffusion of the tubercle bacillus in the peritoneal cavity, either through the circulation or by rupture of a tubercular abscess into the peritoneal cavity, or by extension from a tubercular salpingitis, occasionally gives rise to a form of acute peritonitis characterized as such in a modified way by the clinical manifestations which accompany it. According to the intensity of the infection, or the degree of susceptibility of the patient to the action of the tubercle bacillus, the disease assumes one of the following pathologic forms: (1)

Tubercular ascites. (2) Fibrinoplastic peritonitis. (3) Adhesive peritonitis. Suppuration takes place only when the tubercular product becomes the seat of a secondary mixed infection with pus microbes.

5. CLINICAL CLASSIFICATION.

A diagnosis for the careful physician and conscientious surgeon must include the location, extent, causation, and pathology of the disease. From the information obtained from the classification already made must be obtained the material upon which to base a clinical classification. Such a classification should serve as a guide in differentiating between the cases which demand surgical intervention and the cases which can be trusted to medical treatment.

a. Ectoperitonitis.—Abscess formation in the subperitoneal connective tissue, as seen most frequently in the pelvis in women, in the cavity of Retzius in men, and in the retroperitoneal space in both sexes, is always attended by inflammation of the under surface of the peritoneum. Such abscesses should be recognized and accurately located sufficiently early to prevent serious complications by an extraperitoneal incision and drainage; or, if the abscess is of a tubercular nature, by tapping, evacuation, and iodoformization.

b. Diffuse Septic Peritonitis.—This form of peritonitis is characterized clinically by the gravity of the general symptoms from the very incipiency of the disease; pathologically, by the rapid diffusion of the infection over the entire serious surfaces, visceral and parietal; and, bacteriologically, by the presence in most of the cases of the streptococcus pyogenes in the inflamed tissues. Staphylococci, pneumococci, and the colon bacillus may also be the cause of rapidly spreading diffuse peritonitis. This form of peritonitis usually follows penetrating wounds of the abdominal cavity, complicated by visceral injuries of the gastro-intestinal canal, contusion or laceration of any of the abdominal or pelvic organs, rupture of an abscess or ulcer into the free peritoneal cavity, or the extension of a septic lymphangitis from any of the abdominal or pelvic organs to the peritoneum. Strict aseptic precautions have succeeded in greatly reducing, but not entirely eliminating, the danger from this source in all operations requiring opening of the free peritoneal cavity. In genuine cases of diffuse septic peritonitis surgical intervention is usually powerless in preventing speedy death from toxemia.

c. Perforative Peritonitis.—Perforative peritonitis is manifested by the sudden onset of the disease, by diffuse pain and tenderness, rigid abdominal walls, fever, and vomiting, and by the impossibility by inspection, palpation, or auscultation to ascertain intestinal peristalsis, the latter being almost positive proof of the presence of gas in the free peritoneal cavity. According to the author's observations, meteorismus peritonei in perforative peritonitis caused by affections of the appendix is rare, while he has seldom found it absent in perforations of any other portion of the gastro-intestinal canal. According to the number and virulence of the microbes which find their way into the peritoneal cavity with the extravasation, the resulting peritonitis is either diffuse or more or less circumscribed. The colon bacillus is invariably present in the inflammatory product, but, in addition, streptococci, staphylococci, putrefactive bacilli, the typhoid bacillus, or bacillus of tuberculosis, according to the nature of the primary affection, may also be found.

Perforative peritonitis must be regarded and treated as a strictly surgical disease. The primary lesion must be exposed and treated as soon as a diagnosis can be made, and the necessary measures applied to limit the extension of the infection and to prevent death from toxemia.

d. Circumscribed Peritonitis.—The symptoms appear suddenly, *i. e.*, are preceded by those incident to the primary disease. The severity of the pain and the extent of the muscular rigidity and tenderness will correspond with the extent of the disease. The intensity of the general symptoms are determined more by the nature and virulence of the microbic cause than by the size of the peritoneal surface involved. The inflammatory focus may be limited to a very small space, or it may involve the greater portion of the peritoneal cavity and organs which it contains. Circumscribed suppurative peritonitis is usually the result of infection with staphylococci, bacillus coli commune, and pneumococci. In fibrinoplastic peritonitis surgical interference becomes necessary only when intestinal obstruction is caused by the adhesions. In circumscribed suppurative peritonitis the pus should be evacuated as soon as the disease is recognized, and, if possible, by an extraperitoneal route.

ADDRESS ON THE UNVEILING OF THE BRONZE STATUE OF THE LATE PROFESSOR SAMUEL DAVID GROSS IN WASHINGTON, D. C.[1]

By WILLIAM W. KEEN, M.D.,
OF PHILDELPHIA;
PROFESSOR OF THE PRINCIPLES OF SURGERY AND OF CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

SAMUEL DAVID GROSS was born near Easton, Pa., July 8, 1805, and died in Philadelphia, May 6, 1884, having nearly completed his seventy-ninth year. His early years were spent amid the rustic labors and healthful pleasures of a Pennsylvania farm. This gave him a strong and vigorous body, without which he never could have performed a tithe of the labor which preeminently distinguished his long life. Before he was six years old he determined to be a surgeon, and early in his professional studies to be a teacher. Yet when he was fifteen he knew scarcely any English. Brought up among the sturdy, honest, laborous Pennsylvania Dutch, he could speak that curious English-German. But his English, of which he became so fluent a master, and even pure German, which he began to study at the same time, were learned almost as foreign tongues, and as a result of his appreciation at that early age of his need for a better and wider education.

---

[1] Abstract from the address delivered before the Fourth Triennial Congress of American Physicians and Surgeons, Washington, D. C., May 5, 1897.

At seventeen he began the study of medicine as the private pupil of a country practitioner, but after learning some osteology with the aid of that tuppenny little compend, Fyfe's Anatomy, and a skeleton, he gave up in despair, for again he found his intellectual tools unequal to his work. Accordingly he stopped at once in his medical career and went to the academy at Wilkesbarre. At nineteen he began the study of medicine again—a study in which for sixty years his labors never for a moment ceased or even relaxed.

In 1828, at the age of twenty-three, he took his degree in the third class which graduated from the Jefferson Medical College. He opened an office first in Philadelphia, but soon removed to Easton. Nothing is more characteristic of the man than that, while waiting for practice, he spent hours daily in dissecting in a building he erected at the back of his garden, and provided himself with a subject by driving in a buggy all the way from Easton to Philadelphia and back; wrote a work on descriptive anatomy, which, however, he never published, and in eighteen months after graduation had translated and published Bayle and Hollard's "General Anatomy," Hatin's "Obstetrics," Hildebrand, on "Typhus," and Tavernier's "Operative Surgery"—works aggregating over eleven hundred pages. His motto was indeed "*Nulla dies sine linea.*" His "stimulus," he himself says, "was his ambition and his poverty."

In 1833, five years after his graduation, he entered upon his career as a teacher—a career which continued for forty-nine years, till within two years of his death. This took him first to Cincinnati as Demonstrator of Anatomy in the Medical College of Ohio. In 1835 he became Professor of Pathological Anatomy in the Cincinnati Medical College.

His book on the "Bones and Joints" had appeared in 1830, and next, as the result of four-years' study and teaching, his "Elements of Pathological Anatomy" was published in 1839. In 1840 he went to the University of Louisville as Professor of Surgery, and, excepting one year when he was Professor of Surgery in the University of the City of New York, he remained there for sixteen years, happy in his family, his students, his flowers, and his generous hospitality. He and his colleagues—Drake and Austin Flint—soon made it the most important medical center in the West, and he was in surgery the reigning sovereign. While there he published, in 1851, his work on the "Urinary Organs," and in 1854 another pioneer work, that on "Foreign Bodies in the Air Passages." His fame had become so great that he was invited to the University of Virginia, the University of Louisiana, the University of Pennsylvania, and other schools. But he was steadfast to Louisville until his beloved *alma mater* called him to the chair just vacated by Mütter. From 1856, when in his introductory he said, "whatever of life and of health and of strength remain to me, I hereby, in the presence of Almighty God and of this large assemblage, dedicate to the cause of my *alma mater*, to the interest of medical science, and to the good of my fellow-creatures," till he resigned his chair in 1882—nay, till his death in 1884—this was absolutely true. Even when the shadows of death were thickening he corrected the proof sheets of two papers on "Wounds of the Intestines" and "Lacerations Consequent upon Parturition," his last labors in the service of science and humanity.

Three years after he entered upon his duties at the Jefferson he published his splendid "System of Surgery"—a work which, though in many respects its pathology and its practice are now obsolete, is a mine of information, a monument of untiring labor, a text-book worthy of its author, and has been the companion and guide of many generations of students. From his removal to Philadelphia till his death, twenty-eight years later, his life can be summed up in a few sentences: daily labor in his profession, editorial labor without cessation for some years in managing the *North American Medico-Chirurgical Review*, the successor of the Louisville *Medical Review*, of which he had also been the editor; article after article in journals; address after address; twenty-six annual courses of lectures on surgery to thousands of students; labors without ceasing till he wrapped the drapery of his couch around him and calmly passed away.

In reviewing his life we may fittingly consider it from the standpoint of the surgeon, the author, the teacher, and the man.

As a surgeon he was painstaking, thorough, and careful in his investigation of a case, skilful as an operator, and, having so vast an experience and equally extensive acquaintance with the wide literature of his profession, he was scarcely perplexed by the most difficult case, and rarely at a loss as to the proper course to pursue in the most unexpected emergencies. He was a practitioner of the old school, who always mingled medicine with surgery, and attributed much of his success in the latter to his experience in the former. His influence on the profession was marked and wholesome. He founded two medical journals, was the founder of the Pathological Society of Philadelphia and of the Philadelphia Academy of Surgery, the founder and first president of the American Surgical Association, and the first president of the Alumni Association of the Jefferson Medical College. It is peculiarly fitting, therefore, that these last two associations should unite to-day in erecting and unveiling the bronze statue of one who did so much for them and whom they rightly delight to honor.

As an author, his chief characteristics were untiring industry, comprehensiveness, methodical treatment of his subject, and a singular felicity of style, especially for one who acquired English so late and with difficulty. He "blazed" more than one new "trail" in the forests of surgical ignorance. In the early part, and even in the middle of this century, it was rare for an American to write a medical book. The most they did was either to translate a French or a German work, or to annotate an English one. He was one of the earliest to create an American medical literature of importance, and his works on the "Urinary Organs," on "Foreign Bodies in the Air Passages," and his text-book on "Surgery," gave a position to American surgery abroad which we can now hardly appreciate; while his "Pathological Anatomy" was the very first work in the English language on that most important branch of medicine. His experiments and monograph on "Wounds of the Intestines" laid the foundation for the later studies of Parkes, Senn, and other American surgeons, and have led to the modern rational and successful treatment of these then so uniformily fatal injuries. He first advocated abdominal section in rupture of the bladder, the use of adhesive plaster in fractures of the legs, amputation in senile gangrene, and the immediate uniting of tendon to tendon when they were divided in an incised wound. Had he lived but a year or two longer bacteriology would have shown him that scrofula was of tubercular origin, and not, as he so firmly believed and vigorously taught, a manifestation of hereditary syphilis.

That his eminence as an author should have met with recognition from scientific organizations and institutions of learning is no cause of surprise. It made him the president of the International Medical Congress of 1876, a member of many of the scientific societies of Europe as well as America, and won for him the LL.D. of the University of Pennsylvania, and I believe the unique honor in America of having had conferred upon him the highest degree of all three of the leading universities of Great Britain—Oxford, Cambridge, and Edinburgh.

As a teacher he was earnestness itself. Filled to overflowing with his subject, his one desire was to impart to us as much of the knowledge he possessed as our young heads could hold. Repetition did not blunt the novelty nor time the attraction of his theme. His whole heart was in his work. Especially did he inculcate the principles of surgery, for he was convinced, and rightly, that one who was thoroughly imbued with these could not go far wrong in his practice. As a man, he was beautiful in his relations to his family, who were devoted to him with an affection that was unusually strong; upright in all his dealings, and despising cant and pretense and anything unworthy a true gentleman. Few men were more widely known in and out of the profession, and few ever had the good fortune to know intimately so many distinguished people of both continents. Wherever he was known he was respected, and by those who knew him intimately he was beloved.

Such, then, was the man whom we are gathered to-day to honor. The American Surgical Association, the Alumni Association of the Jefferson Medical College, and a few friends who have gladly united with us in this service of affectionate remembrance, have presented his statue to the people of the United States, to stand forever in our beautiful capital city as a mute yet eloquent evidence of our esteem for his personal worth and his professional attainments.

Yonder statue of Joseph Henry has stood alone for too many years. We have to-day unveiled its worthy companion. Both of them are memorials of men great in science, whose lives were devoted to the good of their fellow-creatures, to saving life, adding to human comfort, lessening pain, promoting knowledge, cheering the sick, and assuaging even the very pangs of the dying. We do well thus to honor in imperishable bronze the men who have won these victories of peace! To no one can the words of the blessed Master apply with greater force than to the kind surgeon whose time and thought and talents are given to humanity, and, above all, to the poor, with no payment but the grateful look of returning health and rescued life and that inward satisfaction which far surpasses all the wealth of the Orient—"Inasmuch as ye have done it unto one of the least of these, my brethern, ye have done it unto Me."

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, MAY 8, 1897.

THE MEDICAL CONGRESS AT WASHINGTON.

ELEVEN years have elapsed since the American Surgical Association first advocated the organization of a general congress of American physicians and surgeons that should assemble at certain stated intervals. The adoption of the plan marked an era in the medical affairs of this country, and now for the fourth time, by the session just brought to an end at Washington, the success attained has demonstrated its ever-increasing value. The component societies of the Congress embrace all the principal departments of medicine, and the membership of each includes men who stand at the head of the profession in their particular line of work. The Congress is a common meeting ground for all, and the clinician and the pathologist thus enjoy opportunities for the comparison of experiences that otherwise would be wanting.

The fourteen societies held individual meetings during the mornings, and in the afternoon all came together in general session. As a rule, the papers presented, and the discussions, were of an eminently scientific character, and in keeping with a much-to-be-desired conservatism.

One of the most interesting events of the Congress was the unveiling of the statue of the late Professor Samuel D. Gross, which occupies a commanding position in the grounds of the Smithsonian Institute. Dr. Keen, in his address, paid a tribute to the memory of this famous American surgeon which will be appreciated by those whose good fortune it was to be associated with him.

The social side of the meeting was marked by many pleasant features, not the least of which was the reception at the Arlington Hotel on Wednesday evening after the address of Dr. Welch, the President of the Congress.

With the celebration of the semi-centennial anniversary of the American Medical Association at Philadelphia in June, and the meeting of the British Medical Association at Montreal in August, this Congress forms a galaxy of brilliant medical conventions that will signalize the season of 1897 as the epochal point of the closing years of the century. It is interesting to note, also, that this work will be supplemented by the coming International Medical Congress at Moscow, but in spite of the importance of the latter, it is more than probable that the practical suggestions that will be of most service to the profession of America will be found in the transactions of the three great societies that hold their meetings on this side of the Atlantic.

The report of the proceedings of the Fourth Triennial Congress, as published in this issue of the NEWS, is especially full and complete, and in order to present it to our readers the number of pages of text has been increased to forty-two. The same enterprise that characterizes this presentation will be maintained in reporting the transactions of the American and British Associations.

ECHOES AND NEWS.

Officers of the American Gynecological Association.—At the recent meeting of this society at Washington, the following officers were elected for the ensuing year: President, Dr. Paul F. Mundé of New York; secretary, Dr. J. Riddle Goffe of New York; treasurer, Dr. J. M. Baldy of Philadelphia.

Sad Result of an Explosion at the Woman's Hospital, New York.—An explosion in the laboratory of the Woman's Hospital on the afternoon of April 29th resulted in the death of Dr. Leo Ross, the first assistant house surgeon, and the injury of Mr. A. S. Wolf, the druggist of the institution. While sterilizing a quantity of catgut in alcohol over a flame, the fluid ignited and was scattered over the men. Mr. Wolf, with rare presence of mind, threw himself on the floor and smothered the flames by means of a coat which he wrapped about himself, but Dr. Ross ran across the yard and into one of the operating rooms, where an operation was in progress. Water was thrown upon him and his clothing removed as quickly as possible, but not before his body had been terribly burned. The unfortunate man died early on the following morning.

Obituary.—Dr. Traill Green of Easton, Pa., died in that city April 29th at the advanced age of eighty-four. Few physicians in Pennsylvania were so widely known and respected as Dr. Green, and his loss will be greatly felt. He was graduated from the Medical Department of the University of Pennsylvania in 1835, and in 1837 was appointed professor of chemistry at Lafayette College. Four years later he was called to the chair of natural sciences at Marshall College, and in 1866 the honorary degree of LL.D. was conferred upon him by Washington and Jefferson College. He was the first president of the American Academy of Medicine. He took a deep interest in all scientific matters, and his name has been connected with many famous works. A number of years ago he erected the Astronomical Observatory at Lafayette College at his own expense and presented it to that institution. In addition to a large number of pamphlets and addresses, he was the author of a work on "The Zoological Floral Distribution of the United States." To Dr. Green probably belonged the distinction of being the oldest continuous subscriber to one medical journal in this country. Under date of December 15, 1893, he wrote to the publishers of *The American Journal of the Medical Sciences* as follows: "For more than fifty years I have been a reader of your journal, and during all these years no journal has been received in my office which has been so welcome or so useful to me, and now as I am beyond four score years of age and about to retire from the active work of my profession, I desire to thank you for the help you have been to me."

SOCIETY PROCEEDINGS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Fourth Triennial Session, Held at Washington, D. C., May 4, 5, and 6, 1897.

[Specially reported for the MEDICAL NEWS.]

GENERAL SESSION.

FIRST DAY—MAY 4TH.

THE first general session of the Congress was nearly a half hour later in assembling than the time announced in the program, and the audience was at first very small. This was due chiefly to the somewhat tardy adjournment of the sections which held meetings in the forenoon.

The meeting was called to order by DR. LANDON CARTER GRAY, of New York, Chairman of the Executive Committee, who, without formal address, remarked that those present who were familiar with the written and unwritten history of the Congress might feel proud at this fourth meeting. The work done in the various component associations and the work to be done in this is sufficient evidence of the activity which is holding its own with the rivalry of the various medical congresses of the present time. After expressing thanks for the honor of having the privilege of opening the Congress, the speaker introduced the President, DR. WILLIAM H. WELCH of Baltimore.

Dr. Welch, in assuming the chair, remarked that he would follow the example of the Chairman of the Executive Committee and not make this the occasion for a formal address. The success of the Congress, he said, depends upon scientific work, of which the program promises an abundance. He also thanked the Congress for the honor conferred upon him by electing him to his office, as well as the officers of the Congress who had worked so faithfully in arranging the program, from the character of which he believed that their efforts would be well rewarded.

The chairman then announced a

BUSINESS MEETING

of the Congress, called in accordance with a resolution passed at the last meeting.

DR. WILLIAM K. SIMPSON of New York explained the nature of the business before the session.

Dr. Simpson stated that the question before the meeting was the consideration of a motion of Dr. White made at the last meeting and laid upon the table, but subsequently reconsidered and made the special order of business at this session. The motion was that the name Washington be stricken out of the by-laws of the Congress as the invariable place of meeting, and that it be left to the will of the Congress at each meeting to select the place for the next meeting.

DR. C. H. MASTIN moved that the question be laid upon the table. This was carried. Dr. S. C. Busey of Washington then moved that the vote just taken be reconsidered and that this present motion be laid upon the table. This motion was also carried.

GENERAL BUSINESS

being made the order of the day, DR. JOHN B. ROBERTS of Philadelphia offered a resolution to the effect that the Executive Committee be instructed to obtain reduced railroad rates for those desiring to attend future meetings of the Congress. Carried.

DR. S. C. BUSEY then reported that he had been instructed by a certain committee on vivisection now in session in this city, and composed of representative men from scientific, educational, and medical institutions, to report to this body and request such action as it may deem proper. A bill is now before the Senate which has been twice reported upon favorably. Twice this committee had strongly opposed the passage of the bill and they thought that their opposition had, in part at least, prevented the vote of the Senate. These two protests were simply scientific documents in favor of vivisection. They had, however, lost to the opposition some of its best friends and they felt that something more should be done, lest these lost friends might become open enemies. The speaker had recently addressed a letter to Senator McMillan, asking for an opportunity to appear before the committee to which the antivivisection bill had been referred, but the only reply was a statement that his letter had been received and referred to the committee. There is danger every day that the matter may be called up before the Senate and the bill enacted without further opportunity being given for opposition. Another difficulty heretofore was the fact that when a notice was given to any committee or individual to appear before committees of the Senate, sufficient time was hardly given for the person notified to get to the Capitol. He desired, therefore, that the Congress of Physicians and Surgeons should protest against the passage of the bill, in the hope that a protest from a body of such scientific prominence as this might carry more weight. He also requested that the Chair appoint a committee with power to take any action in its judgment proper for preventing the passage of this bill.

SURGEON-GENERAL STERNBERG corroborated the statement of the last speaker in regard to the lack of opportunity to prepare any defense when called upon by the Senate committee, and requested that the committee to be appointed by the Chair should consist of non-residents of Washington. He remarked further that the strongest possible resolutions against this bill had been presented to the committee of the Senate, but that it was very doubtful whether such resolutions were ever read by a large number of the committee and hence they were of comparatively little effect.

The Chairman of the Committee of Arrangements then announced various receptions and entertainments for the benefit of members and guests of the Congress. Among these was a reception by the President of the United States on Wednesday afternoon, a dinner at the Arlington in the evening, and a "smoker" by the Cosmos Club, Thursday evening.

The hour for the regular session of the Congress having arrived, the chairman announced as the subject of consideration,

THE GOUTY AND RHEUMATIC DIATHESES AND THEIR RELATION TO DISEASES OF THE EYE.

The first paper announced was that of DR. CHARLES STEDMAN BULL of New York. The title of the paper was

LESIONS IN THE RETINAL VESSELS, RETINA AND OPTIC NERVE, ASSOCIATED WITH GOUT. (See p. 578.)

DR. S. OLIN RICHEY of Washington followed with a paper, entitled

GOUT AND RHEUMATISM AS FACTORS IN THE ETIOLOGY OF GLAUCOMA.

The essayist premised the reading of his paper by a few remarks in support of the positions taken by the previous speaker.

He then said that the least confusing presentation of the subject is under its two extreme forms, acute inflammatory glaucoma and chronic simple glaucoma. All other varieties occur between these two, partaking more or less of one or the other, due to the same cause in different degrees of intensity; including secondary glaucoma, so-called, which may be secondary to keratectasia, or fistula of the cornea, to iridocyclitis, or retinal hemorrhage, dependent upon gout; occlusion of the pupil, luxation of the lens, intra-ocular tumors, choroiditis, myopia—any of these, he said, may cause the increase of tension of a pseudoglaucoma, but not the intra-ocular tension of true glaucoma.

The essayist then presented the following propositions:

1. Increased intra-ocular tension in glaucoma is caused chiefly by distension of the blood-vessels internal to the sclerotic; rarely, and to slight degree, by derangement of intra-ocular secretion, or excretion.

2. Associated with increased intra-ocular tension is high general arterial tension, or arteriosclerosis, pulsation of the intra-ocular arteries and veins, with probable hypertrophy, but at least functional disturbance, of the heart.

3. As a result of persistent venous stasis, thrombosis and hyperplasia of connective tissue with substitution (substitutive fibrosis) takes place in all the tissues of the bulb.

4. In chronic glaucoma, the *materies peccans* of rheumatism cannot be excluded as a factor in causation. No reason appears for suspecting it of any agency in acute glaucoma.

5. Every form of glaucoma is owing primarily to gout (or goutiness) or to acquired syphilis in its tertiary stage.

6. Iridectomy, the first violence of the attack being past, so reduces intra-ocular pressure as to permit the venæ vorticosa to be emptied, thus restoring the intra-ocular circulation and establishing normal tension. Any operation which lessens the surface pressure upon the vascular system within the eye, whatever the result, seems in reason open only to this explanation, for such vessels have no vasomotor system and no power of contraction, but dilate and contract in response to the greater or less force of the extra-ocular blood current.

The essayist then considered the various influences, physiologic and pathologic, which influence intra-ocular tension. He thought that the only rational explanation of the benefit which follows iridectomy in glaucoma is, that a happy moment is chosen when the first force of the storm is spent, and the operation, by easing the pressure upon the intrabulbar tissue and vessels, permits a removal of the venous stasis, and the active circulation to be restored.

Reasoning directly and by exclusion from unquestioned facts led the speaker to the conclusion that a condition always found in acute glaucoma which will account for all its features offers the true explanation of this form of disease. This he stated as follows: A great engorgement of the intra-ocular blood-vessels, overfilling the space within the sclerotic, most so posteriorly, about the entrance of the short ciliary arteries, and the two long ciliary arteries which pierce the sclerotic at a right angle, elongates the corpus vitreum in the direction of the length of the vessels by lateral pressure which is increased by the acute venous stasis and the advancing of the corpus vitreum, lens, and iris, by pressure from behind. This reduces the depth of the anterior chamber, and applies the iris to the cornea, thus obstructing the anterior channels of filtration, and thus produces increase of intra-ocular tension.

The engorgement of the fundus oculi existing in acute glaucoma, always in direct ratio to the violence of the attack, shows it to be directly vascular in origin. A state of the system which leads to a reduction in the caliber of the peripheral arterial vessels, demanding an increased effort on the part of the heart, will account for this.

Whether the intra-ocular vascular engorgement is ever excited by the precipitation of sodium biurate within the eye or not, the author thought, would probably be settled by accidental observation. He did not believe it necessary to assume such a possibility.

Turning his attention to chronic simple glaucoma the essayist remarked that this differed so much from the other forms of the disease that some observers had been led to doubt whether it be glaucoma at all. He, however, considered it glaucoma, a chronic interstitial ophthalmitis. It is of slow development, preceded for years by a slowly increasing intra-ocular tension, with palpitation and uncertain action of the heart. Age is a predisposing factor only, as may be also a neoplasm found within the orbit. The important factors in the arthritic diathesis, the author believed, are an excess of uric acid and an excess of lactic acid—he holding the theory that this acid is the cause of rheumatism. He did not accept the belief of Haig that both gout and rheumatism are due to uric acid.

The essayist then considered at some length the similarities and dissimilarities between the gouty and rheumatic diatheses, with abundant references to the literature of the subject.

The next paper was read by DR. S. D. RISLEY of Philadelphia. Its title was

CATARACT AND ITS ASSOCIATION WITH THE GOUTY AND RHEUMATIC DIATHESES.

The essayist did not think it difficult to trace a distinct relationship between a large group of ocular affections and the lithic acid diathesis. In support of this, he referred to the frequency with which ocular manifestations, as well as the general health of persons suffering from eye symptoms, improve by a change to out-door life with attendant muscular exercise, deeper breathing, and increased excretion. He thought that not only the relationship of this diathesis to the milder forms of ocular trouble is overlooked, but that too often we fail to recognize the relation which exists between it and the more serious affections of the eye that occur especially during and after middle life.

The diseases of the heart and general vascular tree, the renal and hepatic complications, associated with and in some sense dependent upon impairment of the ultimate processes of nutrition, the high arterial tension, the hypertrophied left ventricle, the chronic nephritis, and contracted kidney, the rigid arterial walls becoming atheromatous, angina, apoplexies, present a picture of serious disease which we are too often called upon to treat.

It is not to be supposed that under these conditions the ocular blood-vessels can escape the disaster which has fallen so heavily upon the general vascular system, or that the eye alone should escape the general impairment of the nutritive functions. We are rather prepared to expect the striking picture of disease so frequently presented, when we recall the fact that the choroid is a mesh of blood-vessels ramifying in a stroma of loose connective tissue. In the steadily advancing degeneration of the retinal blood-vessels in glaucoma, we see the arterio- and phlebo-sclerosis, the formation of yellowish-white spots of exudation in the region of the macula or between the macula and optic nerve, or possibly more widely distributed, or the innumerable small retinal apoplexies of hemorrhagic retinitis. In later stages of nephritis, or perivasculitis and hemorrhagic glaucoma, and also the choroidal disease which so often precedes cataract, these changes in the blood-vessels the essayist believed had in many cases been going on for years before the ocular defects became apparent. It is this fact he thought which made these ocular hemorrhages so ominous of cerebral apoplexy. The fact that these changes are usually found in or after middle life, had drawn too much attention to age as an etiologic factor.

Hard cataract has been regarded as a development of old age to the exclusion of other influences in its production. It should be borne in mind, he said, that while the lens loses its elasticity and becomes hard or even straw colored as age advances, it is only in exceptional instances that it loses its transparency to a degree which seriously impairs the acuity of vision. When therefore the lens undergoes not only this physiologic hardening but becomes also opaque it should suggest the presence of pathologic causes for this remarkable occurrence.

It is also true that opacity of the lens occurs in cases in which we can discover no evidence of the rheumatic or gouty diathesis either in themselves or their ancestors, yet even in these individuals the incipient cataract is so uniformly preceded by retino-choroidal disease and vitreous degeneration as to enforce the opinion that the opacity of the lens is a result of impaired nutrition caused by the associated affections of the uveal tract. The essayist adduced sixty successive cases from practice in more than half of which there had been a long period of asthenopia and "weak eyes" before the occurrence of cataract. In them he said there could be no doubt of the relation of cause and effect between the advancing opacity of the lens and the attending pathologic conditions of the uvea.

It is not surprising that the lens and vitreous body should undergo degenerative changes as a result of pathologic processes affecting its food-bearing membrane. The less vicious forms of uveal disease may also be influential in leading to impairment of nutrition of the lens and causing it to become opaque and that the gouty and rheumatic diatheses are among the most frequent causes of these chronic subacute forms of disease affecting the uvea. Careful study would reveal that the entire choroidal tract is more or less seriously involved in every case. It not infrequently happens that the recurrence of iritis is due to the lighting up of latent choroiditis under exacerbations of the rheumatic or gouty diathesis. All attacks do not pass to iritis, but each attack affects more and more profoundly the nutrition of the eyeball. Such attacks are often attended by transient increase of tension, a steamy cornea, and foggy, vitreous body. Examination with a lens resolves this want of transparency into fine granular deposits in the vitreous, which clear up as the attack subsides. Upon repeated exacerbations, fine web-like opacities form, which float more freely as the vitreous degenerates and loses its normal consistency. The nucleus of the lens becomes more and more plainly outlined and the lens substance more reflecting. In many cases banks of opacity form in the periphery, from which spicules of opacity sooner or later project along the capsule toward the pole.

The essayist then reported at some length the history of a case which he had had under observation for a number of years, and in which the conditions were as he had described in the above report. In conclusion, he adduced a number of other considerations which confirmed his belief that the changes in the lens, choroid, and retina may be brought about by the rheumatic or gouty diathesis.

The next paper was by Dr. ROBERT SATTLER of Cincinnati upon

GOUTY AND RHEUMATIC AFFECTIONS OF THE UVEAL TRACT.

He called attention to the fact that in the history of gout mention is early made to the affections of the eye, especially of iritis (ophthalmia arthritica). Much later other parts of the uveal tract were also recognized as the seats of gouty and rheumatic affections, the ocular lesions either arising primarily from this part or appearing secondarily, and associated with similar lesions in other parts of the eye. He then referred to the positive knowledge we possess in regard to the clinical manifestations of gout and rheumatism, although their etiology and pathology remain somewhat obscure. The remainder of his paper may then be briefly summarized as follows:

1. Can gout or rheumatism be considered the principal etiologic factors in those cases of iritis and irido-choroiditis in which a searching examination fails to disclose that the disturbances of the joints are dependent upon syphilis, gonorrhea, chronic lead intoxication, malaria, anemia, and other actual or alleged constitutional causes?

This, the speaker said, is generally admitted, although with varying stress.

2. As to the relative frequency of gout, and rheumatism producing ocular lesions, the major share is assigned by Hutchinson to gout, while the liability to iritis is held to decrease in proportion to the prominence of purely rheumatic symptoms.

The essayist stated that it had been his experience to meet with a rather large number of cases of iritis which must be classed as rheumatic affections.

3. At what period are iritic and other affections of the uveal tract apt to occur? Are they more common during the acute outbreaks of local gout or rheumatism, or during the latent periods of these affections?

In answer to this question, the speaker thought that, as a rule, ocular complications appear during the early manifestations of the uric acid diathesis, or during the stage which precedes for a longer or shorter period acute outbreaks of either gout or rheumatism, or during the intervals of acute or subacute recurrent attacks. He could find no evidence on record to show that they ever occurred during the acute attacks. If such were observed, he would regard it as nothing more than a mere coincidence.

4. Do the ocular disturbances, and particularly the lesions of the uveal tract, offer confirmatory evidence for any one of the many theories advanced to explain the morbid changes which affect the joints, tendons, and fibrous tissues in gout and rheumatism?

It was answered, that there was nothing distinctive which would enable us to recognize without fail, the iritis or irido-choroiditis of gout or rheumatism.

5. For clinical purposes, we may speak of three stages in the process of gout and rheumatism: (*a*) During the stage before local gouty or rheumatic invasions of the joints occur, we can hardly speak of gout or rheumatism as such, but must look upon these manifestations as goutiness, or a rheumatic or rheumatoid tendency. (*b*) After the malady declares itself, it may happen that its characteristics may be preserved for a long time, or even become permanent. (*c*) As either disease progresses or develops, it may partake more or less of the characteristics of the other until such an intimate blending takes place that by common consent it is termed "rheumatic gout."

In the stage of goutiness and of early gout, we meet with the typical "hot eye" appearance of the English ophthalmologists, but rarely with primary or isolated gouty iritis. The most frequent, and at the same time most treacherous, lesion, however, is an insidious variety of exudative choroiditis which often, in spite of the most rational medical treatment and more conservative surgical measures, necessitates enucleation.

An interesting case was then reported in which an iritis was treated on the theories above stated with success.

The speaker said that we not infrequently meet with lesions of the uveal tract, in which a distinct history is obtained which conclusively suggests either a rheumatic tendency without disturbance of the joints or one in which several undoubted paroxysms had preceded the ocular disturbance. Although the designation "rheumatic" is vague, there being no pathology on which to base it, it is supported by a mass of clinical facts.

The most frequent inflammatory affection due to this cause is iritis, either the acute plastic or the chronic variety. It may be the expression of a general irido-choroiditis or the results of an acute process, beginning and confining itself to the iris or the anterior portion of the uveal tract. It can be held that in the group of rheumatic gout, which is a blending of gout and rheumatism, lesions of the uveal tract and iritis in particular may occur. The speaker's own observations had familiarized him with a number of typical cases conclusively setting forth iritis as one of its common complications. Cyclitis and choroiditis are not so common.

If iritic and other complications occur in persons with acute or chronic joint affections in whom syphilis, gonorrhea, chronic lead poison, and other recognized causes are found, are they more apt to occur if such persons are gouty or rheumatic?

This, the speaker considered an interesting point to determine. Mr. Hutchinson has answered the question for us. It demands and awaits further corroboration. In the only case of gonorrheal rheumatism with iritis which had come under the observation of the speaker, a gouty history was obtained.

Concerning other causes, the experience of the essayist had been too limited to justify him in expressing a definite conclusion, but he inclined to the opinion that a gouty or rheumatic heredity is of considerable importance in exciting or increasing the tendency to iritic or other complications.

RHEUMATIC AND GOUTY AFFECTIONS INVOLVING THE CORNEA, CONJUNCTIVA, AND SCLERA

was the title of a paper read by **DR. R. A. REEVES** of Toronto.

He mentioned the difficulty of proving a rheumatic or gouty affection of the eye, and that, although chronic rheumatism is regarded as a cause of many eye affections, it is only in a certain proportion of cases an affection of the uvea. Yet the *materies morbi* of gout is often present in the system. Along with over-indulgence of appetite and profound worry and care, the relation of the diathesis cannot be ignored. The ophthalmoscope may show the presence of retinitis and choroiditis, and the diagnosis is made at a glance.

So many surface lesions of the eye are now attributed to a micrococcic origin that the essayist feared this factor in etiology might be carried too far, and recommended that the blood and other fluids be more carefully scrutinized.

In corneal affections with these diatheses, we usually find a wide-spread obscuration, resembling in appearance a glass that has been breathed upon. Desquamation of the surface epithelium occurs only exceptionally. An interstitial variety has also been described. This is especially toxemic in character and allied to syphilis. The affections which lead to uveitis may also lead to parenchymatous choroiditis without tendency to suppuration. The iris is exceptionally involved. The process may be associated with indelible sclerosed patches. The treatment consists of hot poultices and local injections of pilocarpin and eserin. De Wecker recommends iridectomy. This would appear to be allied to the catarrhal ophthalmia of which we hear but little at the present time, but which Mackenzie insisted upon a few years ago.

Centripetal corneal ulceration is likely to occur. Band-like opacities of the cornea always give rise to a suspicion of gout. The essayist then reported three cases of ephemeral conjunctivitis in subjects with gonorrhea which appeared to be due to a pseudo, or actually acute rheumatic tendency. Sir Dice Duckworth says that rheumatic and gouty deposits occur in the conjunctiva of the lids.

There is an interesting variety of episcleritis denominated by Fuchs, *episcleritis fugax*, the "hot eye" of Jonathan Hutchinson, more frequent in men than in women, attended by photophobia, lachrymation, and pain, the attacks lasting from one to eight days. The treatment consists of the topical application of pilocarpin. Episcleritis proper is distinguished by several authors as a circumscribed inflammation of the anterior part of the sclera producing later a widely spreading swelling two to five lines in diameter, one to two lines from the corneal margin, never attended by ulceration, but undergoing absorption in the course of weeks or months. It seldom occurs singly, one nodule usually appearing as another disappears. At times there is marked pain and irritability of the eye. It occurs especially in adults, some of whom are subjects of gout, and some of rheumatism. The treatment is the administration of salicylate of soda and the subconjunctival injection of pilocarpin.

Scleritis attacks any part of the globe, is not nodular, and is essentially chronic and recurrent. It is, as a rule, very painful, leaving a dusky, or slate-colored zone. The speaker urged recourse to pilocarpin in the treatment.

The malignant form of uveoscleritis, with staphylomatous swelling and ultimate loss of the eye, is not included, being connected directly with the scrofulous or strumous diathesis, and not with gout, or rheumatism.

DR. J. M. DA COSTA of Philadelphia stated that he thought it well to bear in mind the real nature of the diseases under discussion. In regard to rheumatism, the typical phenomena of swollen joints, acid perspiration, and tendency to heart affections, leave no doubt as to the character of the affection. But in so-called chronic or rheumatic gouty affections there is always doubt, and four-fifths of all cases called chronic rheumatism are not rheumatism at all. We should therefore carefully scrutinize all affections of the eye of the character ascribable to chronic rheumatism. He had no doubt that these would, in the future, be so reduced that there will be very little left of them.

We know more of the pathology of gout than we do of rheumatism. Whether as cause or effect, connected with faulty secretion or faulty excretion, a morbid state occurs in which uric acid is concerned. He doubted the existence of such a disease as rheumatic gout. There is such a disease as rheumatoid arthritis, in which the joints swell and uric acid is not found in the urine. It is not connected with gout or rheumatism. It is of great importance that we learn to associate or disassociate certain eye affections with this disease, and not with gout or rheumatism.

In general practice he had, in acute rheumatism, met affections of the eye, usually inflammatory in nature, ophthalmia, conjunctivitis, and the like. The most common had been conjunctivitis, and sometimes iritis, occurring during the attack of acute rheumatism, sometimes associated with the acute endo- or pericarditis. But gouty inflammation of the eye occurs not only in acute outbreaks of gout, but very frequently when no acute outbreak exists. It is very common to have this affection originate in one eye and then pass to the other. During a long experience, he could scarcely remember an affection of the eye connected with a pure rheumatoid arthritis. Nor do endocarditis and pericarditis occur in this connection.

A certain number of persons have what is called suppressed gout, or, better termed, lithemia. In this, inflammatory affections of the eye are very common. These affections also commonly begin in one eye and pass to the other; sometimes associated with marked attacks of headache. The key to gouty cases is furnished in the careful examination of the urine. In conclusion, the speaker reported the case of a prominent gentleman who suffered from repeated attacks of eye trouble with headache, in whom careful regulation of the diet, with the administration of lithia water and colchicum had resulted in a period of freedom from all symptoms for the last two years. There was no evidence of gout in the case, unless a slight tendency to asthma, but the result of treatment had been sufficient to warrant the conclusion that the eye trouble was due to that diathesis.

A session was now held under the auspices of the American Otolological Association.

A paper was read by Dr. Clarence J. Blake of Boston on

THE RELATION OF OTOLOGY TO GENERAL MEDICINE.

The author remarked that the gifts of otology to general medicine are nowhere more clearly shown than in the diseases of the ear occurring coincidently with the exanthemata of childhood. He insisted upon the importance of early and repeated examinations of the ears of children suffering from the acute exanthemata. Attention was also given to the occurrence of ear complications in diseases of the pleural cavity in childhood.

The importance of testing the hearing of school children should interest and influence the profession at large. The generally received opinion that diminution of hearing in children in consequence of disease is rare, is a mistake. Very nearly 25 per cent. of the patients attending our aural clinics are children under fourteen years of age; of this number 50 per cent. suffer from suppurative inflammation of the middle ear, and of this number 10 per cent. or more owe their origin to the exanthemata, while throughout the United States 27 per cent. of deaf mutes have suffered from suppurative middle ear disease in early childhood.

The surgery of the ear requires a wider range of skill than general surgery. We have not only to attempt to save life, but also to conserve, so far as possible, the hearing power and leave undisturbed the equilibrating function of the ear, and also to avoid injuring important structures closely contiguous to the operative field.

The so-called chronic catarrhal inflammation of the middle ear is one of the most frequent diseases of the ear which come under the consideration of the general practitioner, making in the temperate zone about thirty per cent. of all the material ultimately referred to the aural specialist. Another example is chronic non-suppurative middle ear disease, in which the deleterious changes in the lining membrane of the tympanic cavity are furthered by general nervous over-strain.

One of the most striking examples of the elucidative work of otology is that which relates to the definition and explanation of the curious complex of symptoms of which vertigo is the most marked manifestation. It is now a recognized fact that an effusion or hemorrhage in the labyrinth may affect the hearing or the balancing power or both. Another subject which should command the attention of the aurist and general practitioner is the "fatigue of deafness," a common and often underestimated factor in the causation and persistence of neurasthenia.

In conclusion the speaker urged the importance of a more thorough teaching of otology in our colleges. The inducement which led the student thirty years ago to take up the study of otology, was because it presented a promising domain for original research, and this is as true to-day as it was then.

(Continued on page 608.)

AMERICAN SURGICAL ASSOCIATION.

Eighteenth Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

First Day—May 4.

The President, Dr. John Collins Warren of Boston, delivered an address upon

THE INFLUENCE OF ANESTHESIA ON THE SURGERY OF THE NINETEENTH CENTURY.

The records of ancient history show that physicians and surgeons had in mind the possibility of an agent being discovered, the use of which might prevent pain in surgical operations. Although it has been said that the discovery of surgical anesthesia was a surprise, that its advent was marked by no tentative steps, that it appeared to have had no preliminary experimental stage, yet a retrospective glance at the history of the previous half century will show that the idea was working in men's minds more powerfully than before, and that, as Paget says, a great truth lay unobserved, though it was covered by so thin a veil that a careful physiologic research must have discovered it.

The well-known observations of Davy upon nitrous oxid and Faraday upon the vapor of ether are among the earlier of the reliable records; while of those which immediately led to the introduction of anesthesia into surgical practice the experiments of Colton and Wells with the former and of Long, Morton, and Jackson with the latter stand preeminent. The work of the several Americans who were most active in the application of the discovery began to attract public attention in 1844 to 1846, and it was upon the 16th of October of the latter year that Dr. John C. Warren successfully performed the first surgical operation under anesthesia in the Massachusetts General Hospital, Dr. W. T. G. Morton administering ether. On December 21st, Liston, in London, amputated a thigh and performed an evulsion of the toe nail with perfectly satisfactory results.

Thus the great step was taken, the "thin" veil was suddenly thrown aside, and what had been before a surmise of the scientist, a pastime of the idle student, and the dream of the surgeon, suddenly assumed practical form and shape and became a living truth, revealed in all the fulness of perfection.

The effect upon the practice of surgery was immediate and revolutionary, both in extending its domain and increasing its activity. The record-books of the Massachusetts General Hospital show the total number of operations during the five years following the introduction of ether was over two and one-half times as great as that in the five preceding years.

The question whether anesthetics increased mortality or not was one which was much discussed formerly. Simpson believed that they did not. Arnott brought forward figures to show that the mortality had been increased 12 per cent. in amputation and 28 per cent. in lithotomy. Erichssen also believed the mortality-rate had increased since the use of anesthetics in operative surgery. Curling gives the mortality of amputations of thigh and leg in the London hospitals for 1837 to 1843 at 41 per cent. During 1847, in 73 cases in which an anesthetic was given, the mortality was 19 per cent. At the Pennsylvania Hospital the mortality of amputation from 1835 to 1840 was 36 per cent.; from 1840 to 1845 it was 20 per cent.; from 1850 to 1855 it was 23 per cent., and from 1855 to 1860 it was 31 per cent. At the Massachusetts General Hospital the death-rate was, as a rule, decreased in the different classes of operations. The rapidity with which certain operations were performed undoubtedly favored asepsis, particularly in all aseptic cases, and probably in any operation which could be done quickly and thoroughly. In many cases of spreading sepsis rapidity was a bar to thoroughness, and results were correspondingly unsatisfactory.

When we reflect how few of the aids to surgical diagnosis were possessed by surgeons in 1846, the amount of work which they accomplished presents all the stronger contrast. They had no endoscope, no ophthalmoscope, no modern aspirating-needle, no clinical thermometer, and no laryngoscope. The stethoscopes were far from perfect. Examination of the blood and quantitative analysis of the excretions were unknown. The microscope was just coming into use for pathologic purposes. They possessed, however, an excellent technic so far as operative surgery was concerned. Their capacity for operating was unlimited, but their judgment was not guided by the many aids which serve us to-day.

It is interesting to note, however, the strangely appropriate order in which the great facts of medicine and surgery were given to the world in this progressive century. Hunter had already roused the thirst for knowledge which led others to rush forward and immortalize themselves as pioneers in anatomy, like Bichat, or in modern surgery, like Cooper. Then came the work of the pathologists, such as Cruveilhier, and the host of German pioneers. Just as the surgeon had brought his operative technic to a high degree of perfection, and science had made a practical instrument of the microscope, and preparation had been made for another advance all along the line, then came anesthesia, which widened the field of research sufficiently to occupy the world busily for another quarter of a century. It gave to surgery a more powerful impetus than it did to experimental medicine. At a moment when surgery seemed rushing wildly onward to its own destruction, with science lagging far behind, Lister came to the rescue, and scientific equilibrium was again restored.

"Gentlemen, the Old Massachusetts General Hospital stands as it did in 1846, with its sightly Bulfinch dome and granite columns. From a scientific standpoint it seems an antiquated structure in comparison with the modern pavilion wards, laboratories and operating-theaters which surround it, but it will never be torn down. It will always remain as one of the conspicuous landmarks of this wonderful century—as a shrine of surgery sacred to that moment 'when the fiercest extremity of suffering was steeped in the waters of forgetfulness and the deepest furrow in the knotted brow of agony was smoothed away forever.'"

DR. JOHN HOMANS of Boston read a paper, entitled

THE INDICATIONS FOR AND THE TECHNIC OF HYSTERECTOMY.

The author considered that the uterus should be removed for intractable hemorrhage and for malignant disease, as well as in many cases of uncontrollable prolapse, incurable chronic inversions, cases of infection, and to cure puerperal sepsis. He dwelt at some length upon the technic of hysterectomy, vaginal and abdominal, and a combination of the two methods, described various special manipulations, dwelt upon the importance of the preparation of the patient, and referred to the question of using a Jacques' self-retaining catheter in the bladder after these operations.

DR. H. H. MUDD of St. Louis in discussing this paper said that hysterectomy for fibroid tumors had a technic which was not uniform and which varied with the special indications. He expressed himself as especially gratified to hear that Dr. Homans discards the clamp. In his opinion, hysterectomy for suppurative periuterine inflammations should be strictly limited to a very narrow field. Vaginal hysterectomy for malignant disease is effecient and desirable for those cases where the disease is limited to the external os. The extension of carcinoma of the os is by infiltration of new tissue in two directions; first, along the vaginal tissue, and, second, into the broad ligiments. Most of the cases in which malignant growth begins in the body of the uterus should be subjected to abdominal hysterectomy, as this is certainly the only method of operation where the uterus is secondarily involved. The greater number of cases of malignant disease which require hysterectomy have their origin in the os, and if presented early to the operator may be removed by the vaginal route. The preparation of the patient for these operations is in accordance with the general rule, but the author's preference is to have the patient anesthetized upon the operating table in order that the time necessary for the anesthetic may be as short as possible. The Trendelenburg position is preferable, and the abdominal incision should be free enough to give room for rapid and accurate work. If the growth is soft and pliable, it should be cleansed with a curette, washed with sterile water, wiped with a gauze sponge and the firmer margins approximated by sutures.

After describing at some length the various steps of the operation, the question of the ligature was taken up, and silk was advised to be used in securing the ovarian artery. It may be cut short, or left with one end resting in the vagina. Hemorrhages should be well controlled by ligatures, or by clamps. The author has discarded iodoform gauze in all cases where it comes in contact with the peritoneum, as he considers it a dangerous agent.

Dr. F. E. Lange of New York stated that in his opinion the principal dangers in these cases were hemorrhage and sepsis, and he thought it a good idea to lay down certain general rules to be followed in approaching all these cases. All working in the dark should be avoided. The speaker had occasionally employed a crucial incision in these cases, and in some had made an incision above the symphysis pubis, but found that in some of the crucial operations the fleshy portions do not offer enough resistance, and this is especially true where the patients have not been pregnant before the operation and become so afterward. In some cases such an extensive raw surface has remained after operating that it has been necessary to use the large omentum in order to prevent the agglutination of the intestines. Tha paravaginal, or pararectal incision has also been employed to good advantage, which consists of the separation of all of the soft parts along the side of the rectum. The hemorrhage is considerable in these cases, and it is well to secure the vessels as much as possible before they are cut. The advantage of this incision is that the floor of the pelvis becomes much more accessible. Provision against infection is also greater because the drainage away from the peritoneal cavity takes place.

Dr. Dudley P. Allen referred to an operation in which the patient is placed in the Trendelenburg position, the fibroid is drawn over the pubis, and is separated from the surrounding structures with a pair of scissors. The uterus is divided from the bladder anteriorly by a few cuts of the scissors, and the broad ligament is held between the thumb and finger. This operation, up to the present time, has been very successful.

Dr. Albert Vanderveer of Albany said he agreed with Dr. Homans that when curetting and all intelligent lines of practice had been carried out without recovery for the correction of misplacement, removal of the uterus is the proper procedure. As to the method of removal, he declared himself firm in the conviction that if the vagina is normal, or comparatively so; if the cervix, particularly the external os, is in a healthy condition, the abdominal or supravaginal hysterectomy gives the patient a degree of normal vaginal anatomic relations that is comforting and beneficial to her, in addition to giving the operator an opportunity to examine the pelvis from above, to relieve adhesions, to bring under positive observation the tubes and ovaries, and, if not healthy, to remove them. On the other hand, if there be present decided cystocele, or rectocele, or prolapse of one or both ovaries, then the vaginal route is to be preferred. In his opinion, the clamp should be avoided in the abdominal operation.

He regretted very much the fact that these cases are not brought to the attention of the surgeon before the disease is so far advanced, and referred to the various diseases to which the condition is ascribed, as, for example, supposed change of life or ill-health from the last confinement or miscarriage. Speaking of carcinoma, he considered an operation was called for when it was confined to the uterus, and all suspected symptoms and indications had been confirmed by microscopic examination of specimen removed. When the uterus is not too large from invasion of the body by the disease, when there is no considerable fibrosis present, and when no pregnancy beyond the third month complicates, the surgical route should be vaginal. The presence of a fibroid does not necessarily mean an operation, as many patients suffer so little inconvenience that such a procedure is not called for, and curetting will answer in a few cases. As to the combined operation, panhysterectomy, the author considered that but few cases called for this procedure, but when it is done, surgeons should give themselves the benefit of a free abdominal incision. He objected strongly to taking away any more of the pelvic organs than was absolutely necessary if like good results could be secured by a less severe procedure. In his opinion, it was inadvisable to place a Jacques' self-retaining catheter in the bladder after these operations.

Dr. J. William White of Philadelphia read a paper, entitled

THE X-RAYS IN SURGERY.

He divided the consideration of the subject (1) in its relation to foreign bodies, (2) fractures and luxations, and (3) diseases of bones and joints. He stated that foreign bodies in the cavities of the body could be located by a system of triangulation by means of successive skiagraphs having known relations to one another and to a fixed point on the surface of the body next the plate. Bullets in the cranial cavity have been located and removed, and their recognition is easy in the majority of cases, while in the thoracic cavity they can be located with reasonable accuracy in the trachea, bronchi, lungs, or pleura. Rubber drainage-tubes in the pleural cavity cannot invariably be detected by the Röntgen method, as they seem to be more or less translucent to the rays. Detection of bodies in the esophagus continues to be very satisfactory, and the conditions of foreign bodies in the abdominal cavity are about the same as in the thorax. Bodies in the pelvic cavity can be found by taking skiagraphs with the patient in various positions. With regard to fractures of the skull, it is especially desirable that we should be able to recognize (*a*) fracture of the inner table, (*b*) linear fracture, and (*c*) fracture of the base. Up to the present time there is no case on record of the first two having been done clinically, but it has been accomplished experimentally with entire success. Skiagraphy will doubtless result very beneficially in the future in the prognosis and treatment of fractures and dislocations of the spine, and will no doubt give us great help in obscure cases of fracture of the sternum, scapula, clavicle, and pelvic bones.

On account of the movements during respiration, skiagraphing the ribs is especially difficult, but this movement can be much restricted by a fixed dressing not opaque to the rays. Fracture and luxation of the bones of the extremities can usually be readily demonstrated. Ununited fracture, even in the presence of close fibrous union, can be shown with great accuracy. In disability following old fractures near a joint, skiagraphy has been of the greatest help in determining the mechanical cause of the limitation of motion. Beferring to the medico-legal aspect of this matter, and to the question of whether or not the patient has a right to demand as ordinary care that the medical attendant should have a skiagraph of the fracture taken, the author stated that at the present time he would unhesitatingly answer in the negative. There can be no doubt, however, that skiagraphs will figure largely in suits for damages in the near future. There is no doubt that a definite diagnosis will soon be possible in cases of disease of the bones and joints, and it is evident that skiagraphy has added to the precision of our management of many forms of these diseases. In various forms of cardiac disease, the fluoroscope is likely to be more useful than the skiagraph, as, in the case of organs in motion, the skiagraph can only give the net result during the period of exposure. Referring to the amount of exposure necessary, the author stated that this varies very much, and in the case of stone in the gall-bladder, the thickness of the abdominal walls and the depth of the calculi from the surface played an important part. Renal calculi had been found and successful operations performed based on the skiagraphic evidence, while vesical calculi are more difficult to find on account of the over-lying position of the symphysis pubis. Urethral stone has not yet been seen clinically but seems likely to be easy of recognition. As to the possible therapeutic properties of the rays, they were first thought to be germicidal, but this has since been denied. The author stated that he had directed his attention to the cure of cancer with the rays, and his hopes of success had been somewhat bolstered up by his experience, although as yet he had no results to report. In the meantime he felt confident that no harm could come to the patient, even though the experiment should be unsuccessful.

DISCUSSION.

DR. W. W. KEEN of Philadelphia, in discussing this paper, called attention to the importance of the medico-legal relations of the X-rays, and mentioned a case showing the unreliability of skiagraphs as a means of diagnosis.

DR. CHARLES B. NANCREDE of Ann Arbor dwelt upon the importance of taking skiagraphs in various positions, and quoted cases in support of his statement that one or even two or three pictures should not be used as a basis of diagnosis. He also stated that the fluoroscope will occasionally be successful where the skiagraph has failed, and *vice versa*. He illustrated his remarks with several skiagraphs, and mentioned that an apparatus costing but $50 would throw a spark 7¾ inches and do all that was necessary in the majority of cases.

DR. G. R. FOWLER of Brooklyn dwelt upon the importance of taking a picture in various positions, and mentioned a case in which he was able to demonstrate in a perfectly sound limb an apparent deformity similar to that which existed in a previously injured limb. He also stated that the fluoroscope was often of use when the skiagraphs gave negative results, and laid great stress upon the possibility of defective skiagraphic plates.

DR. M. H. RICHARDSON of Boston showed a number of skiagraphs and emphasized the medico-legal relations of the X-rays. He stated that a number of judges had signified their attention of admitting these pictures as evidence in suits of malpractice.

DR. WILLIAMS showed a number of skiagraphs, and also demonstrated an instrument for showing calculi in the bladder.

DR. CHRISTIAN FENGER of Chicago referred to a case in which search was made for a bullet in the cranium, and in which the soft parts of the skull down to the bone subsequently died, presumably due to too long exposure.

ASSOCIATION OF AMERICAN PHYSICIANS.

Twelfth Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

FIRST DAY—MAY 4TH.

The Association met at 10 o'clock, A.M.

The President, **DR. J. M. DA COSTA** of Philadelphia, in the Chair.

PRESIDENT'S ADDRESS.

The President read his annual address, entitled "Tendencies in Medicine," which will appear in the next issue of the NEWS.

MISCELLANEOUS BUSINESS.

The Council recommended the adoption of the amendment proposed last increasing the membership of the Association from 100 to 125. After discussion this amendment was adopted. Dr. S. C. Busey, Washington, said that he had been requested by the medical staff of the navy to ask that the Association should present resolutions to Congress praying it to enact a law giving the medical staff of the navy a distinct rank, instead of the relative rank now conferred. On motion of Dr. Sternberg, surgeon-general of the army, this was referred to the Council for report.

THE SERUM TEST FOR TYPHOID FEVER.

By **DR. GEORGE B. SHATTUCK** of Boston. He dealt with the cases of typhoid fever occurring in the Boston City Hospital which were tested with Widal's serum. All the tests were made with liquid blood. In the laboratory a longer maximum limit, one hour, was allowed for the reaction than some observers would consider justifiable, though many of the reactions did occur in much less time. The character of the reaction was considered as well as the time within which it occurred. The room culture reacted less promptly than the thermostat culture. Three of the cultures were from the spleens of deceased patients, and one from fluid aspirated from an enlargement, corresponding in position to the gall-bladder, in a patient who was suffering from that disease. Tests made with room cultures had proved so satisfactory that all tests were now made in that way. In these tests the organisms were fewer in number but were larger and more motile, and the reactions, while perhaps a little slower, were so absolute that little difficulty was experienced in making a diagnosis. In the thermostat cultures there was often a small sediment of dead organisms, which if shaken up into the fluid might interfere with the diagnosis. Room cultures could be used for the test when much older than thermostat cultures, the growth being more gradual and the organisms hardier.

An analysis of 116 cases, with a clinical diagnosis of typhoid fever, showed the reaction as follows:

On the 6th day in 1 case.
" " 7th " " 4 cases.
" " 8th " " 6 "
" " 9th " " 5 "
Between the 10th and 15th day 23 cases.
" " 15th " 20th " 16 "
" " 20th " 30th " 32 "
" " 30th " 40th " 13 "
" " 40th " 50th " 11 "
" " 50th " 60th " 5 "
" " 60th " 70th " 2 "
" " 70th " 80th " 2 "
" " 80th " 90th " 0 "
" " 90th " 100th " 0 "

In one case there was a reaction on the 199th day, one on the 110th, one on the 121st, and one on the 122d day. In one case there was no reaction on the 26th day, but it was present on the 27th day; in one case no reaction on the 15th, present on the 16th; in one case no reaction on the 16th or 18th days, present on the 59th day; one case no reaction on 7th day, present on the 9th day; one case no reaction on the 18th day, present on the 45th day.

In five of the cases the serum test gave a positive result, and was of material service in determining a doubtful diagnosis. In one case physical examination was negative; characteristic symptoms were absent, but there was some temperature. There had been cases of typhoid fever in the neighborhood of the patient's home. The serum test gave a good reaction on the twenty-second, twenty-third, and twenty-fourth days. Six weeks before admission to the hospital, the second case recorded suddenly became mentally confused for a short time without losing consciousness. He recovered, but had a similar attack, from which he recovered more slowly and less completely. He was slow in expression and miscalled words. The left leg was swollen and painful on pressure. Blood, albumin, and casts were found in the urine. The attending physician, a practitioner of large experience in typhoid fever, diagnosed serious renal disease, and gave a grave prognosis. On examination in hospital the edge of spleen was felt; otherwise physical examination was negative. Temperature might have been that of the end of typhoid. No diazo reaction. Serum test gave a prompt reaction, and patient made a good recovery.

In eighteen cases with clinical diagnosis other than typhoid fever there was no reaction in fifteen, of which one was phthisis, two pneumonia, two pleurisy, four meningitis, three "febricula," one acute miliary tuberculosis, one appendicitis, one influenza. There was a reaction in three cases—one of pneumonia, one acute miliary tuberculosis, one exophthalmic goiter. In all three of these cases the typhoid reaction was justified, and the test made the diagnosis.

The query having arisen whether the serum from the blood of the negro was more prone than that from the white to produce the reaction, even in the absence of typhoid fever, tests were made on thirteen colored patients with clinical diagnoses other than typhoid. In eight there was no reaction. In three there were reactions more or less satisfactory with thermostat cultures, but none with room cultures. In two there were good reactions. One was a black negress, the other a mulatto born in Africa. They certainly had not had typhoid since entering the hospital, but typhoid could not be excluded from the histories for the previous six months.

The diazo reaction was sought for in 89 of the 125 cases of typhoid fever, and was found in 42 cases and absent in 47 cases. In one case, curiously enough, the diazo reaction was present on the fifteenth day when the serum test was absent, and absent on the fifty-ninth day when the serum test was present.

DISCUSSION.

Dr. A. C. Abbott of Philadelphia said that his experience with the Widal test had been made in municipal practice in Philadelphia, where the conditions were not so satisfactory as in Dr. Shattuck's experience. His, however, corresponded very closely with those obtained at the Boston City Hospital. Out of 68 cases in which a clinical diagnosis of typhoid had been made, the serum test responded in 66.

Dr. J. H. Musser of Philadelphia reported a case which had been brought into the wards of the hospital with no evidence of typhoid fever, but was suffering from marked cerebral symptoms. The serum test was applied, and the reaction was present in a marked degree. Several days afterward meningitis set in and the patient died. In this case the reaction was present all the time, and was the only evidence that the patient was suffering from typhoid.

Dr. William Osler of Baltimore gave an abstract of the experience with Widal's test at the Johns Hopkins Hospital. In forty-four cases the reaction was perfectly satisfactory, and had been found several times very late in the disease. Several cases had been admitted that had suffered primary attacks outside of the hospital, in which a reaction to Widal's test was found. In one case of meningitis the absence of the serum reaction determined the diagnosis.

Dr. W. B. Atkinson of Philadelphia said he would like to know how long the susceptibility of the blood to the Widal reaction would persist. Persons might have had typhoid fever at some previous time, and in a subsequent illness a blood examination would give the serum test.

DR. JAMES TYSON of Philadelphia said that two observations in the use of Widal's test had been made by him which might be of interest. One was a young boy admitted on the seventeenth day of an attack of so-called typhoid fever, having been under the care of a well-trained physician outside the hospital up to that time. He had a temperature ranging from 101° to 103⅕° F., and many symptoms of typhoid. There was no reaction to the serum test, but the diagnosis of typhoid was not changed. He declined rapidly, and the autopsy revealed miliary tuberculosis of the lungs, but no lesions of typhoid fever except enlarged spleen. Another case was that of two sisters, who, after skating on the Schuylkill, had drunk from a hole in the ice. Two days afterward both were taken sick, and both had decided fever and headache, and one had had two attacks of epistaxis. The other had two spots on the abdomen which behaved very much like those of typhoid fever. Two specimens of the blood of the older were examined, the first showing positive, but somewhat slow reaction. An examination of the blood of the younger, sent at the same time, gave a very incomplete reaction. At no time did either have diarrhea. The older never had any spots, while the younger, whose case aborted, and in whom the serum test gave only an incomplete reaction, had only two.

DR. BILLINGS of Chicago said that he had had considerable experience with the use of Widal's test. Failure in its use was often due to the fact that the instructions given by Widal and Johnson were not carried out. The instructions given by the latter were that old culture should be used—that the old culture should be used as a basis, and the new culture made from that. Old cultures were rather easily killed by the blood serum in very many cases, such as septicemia and other surgical diseases. The test was more constantly positive in typhoid fever, and more constantly negative in other diseases.

DR. JAMES T. WHITTAKER of Cincinnati reported a case of the daughter of a physician who was listless, had fever, headache, and a temperature of 100° F. Albumin was found in the urine, and the father thought she had Bright's disease. He came to the conclusion that she had latent tuberculosis, and gave her an injection of tuberculin, but got no reaction. Later he applied Widal's test and got reaction. Had also applied the test in four other cases of ambulatory typhoid, or in protracted convalescence from typhoid, with positive results.

DR. F. C. SHATTUCK of Boston reported the case of a young girl who had been ill for some time with a fever of 104° F. and cerebral symptoms. Afterward the fever abated, but she did not get well, and he was asked to see her. He asked the attending physicians: "Why is this not a case of typhoid?" They said they did not think it was; that it was more like Bright's disease. He took a specimen of her dried blood and examined it by Widal's test and got the reaction. This corroborated the diagnosis in his own mind. The cases of typhoid, complicated with renal symptoms, are misleading, but the outlook is better than if these symptoms exist independently.

DR. JANEWAY said he wished to make a few remarks about the danger of Widal's test. The danger lay in depending upon this test, implicitly, and in its absence, even though the clinical symptoms of typhoid were present, ruling out the diagnosis of typhoid.

GALL-BLADDER INFECTION IN TYPHOID FEVER

was the title of a paper by DR. A. LAWRENCE MASON of Boston.

The speaker said that the normal bile was sterile, but that when the system was weakened by disease the micro-organisms in the duodenum might enter the gall-bladder through the bile ducts. So, when the blood was teeming with micro-organisms they might reach the gall-bladder after a number of days. In a number of cases of typhoid fever complicated with gall-bladder infection, gall-stones had been found. The question arose whether typhoid fever was ever the cause of gall-stones. In nineteen cases recorded associated with gall-stones, they had their first attack of biliary colic after an attack of typhoid fever. As to the treatment, simply tapping the gall-bladder will generally suffice, as in his case, and only in rare cases should laparotomy be resorted to. His conclusions were that the gall-bladder was infected by micro-organisms from the intestines or blood; that gall-stones predispose to the complication; that typhoid fever may lead to the formation of gall-stones in predisposed cases.

HEPATIC COMPLICATIONS OF TYPHOID FEVER.

By DR. WILLIAM OSLER. The rarity of this complication was shown by the fact that in 2000 cases of typhoid fever there were only 5 with inflammatory processes in the liver. The symptoms of the disease and complication very much resemble the appearance of appendicitis. He reported a case of this kind which was operated upon for appendicitis, and when the abdomen was opened it was found that the appendix was normal, but there was inflammatory disease of the gall-bladder, which was very much enlarged. The gall-bladder was tapped, and 100 c.c. of clear fluid removed. The gall-bladder was then packed with gauze, and the patient recovered. Subsequently another operation was performed for the removal of a stone in the gall-bladder. The colon bacillus was present in this case.

DR. WILLIAM T. COUNCILMAN of Boston, in discussing the paper, said that he thought if a thorough examination could be made it would be found that the number of cases in which typhoid bacilli were found in the gall-bladder would be very much larger than was generally supposed. His impression was that they could nearly always be found in a case of typhoid fever. The manner of infection, he thought, was through the blood.

UREA ESTIMATIONS IN CASES OF TYPHOID FEVER TREATED BY THE BRAND BATH METHOD.

By DR. JAMES TYSON of Philadelphia. The paper gave the details of a case of typhoid fever in which the urine examination showed some albuminuria and hyaline casts. In spite of these symptoms the Brand method of treatment was persisted in, and it was found that so far from there being a suppression of urine during the baths the secretion was markedly increased. The albumin bulk remained at one-quarter bulk until fourth day, when it fell to one fifth, and on the seventh day to one-twelfth. After that date it disappeared, and with it the casts. "This is the history of a case of typhoid fever strikingly complicated with conditions which superficial observation would expect to increase any risk to which the patient is subjected by cold bathing, *viz.*, nephritis and deep-seated bronchitis, possibly broncho-pneumonia. So far from aggravating either of these two conditions, both abated and early disappeared."

He said further that the effect of cold baths in exciting secretion of urine has long been recognized, and almost every person who is in the habit of taking a frequent cold bath has experienced such effect in his own person. The sources of urea in the urine in fever are two: (1) the nitrogen in the proteid food ingested; (2) the oxidation of tissue, which is much increased during the fever process. He concluded by saying: "At present my confidence in the hydriatic treatment is such that I would not feel comfortable to treat a case in any other way unless such treatment were insisted upon by the patient."

CANCER OF THE STOMACH IN EARLY LIFE; AND THE VALUE OF CELLS IN EFFUSIONS IN THE DIAGNOSIS OF CANCER OF THE SEROUS MEMBRANES.

By **Dr. George Dock** of Ann Arbor, Mich. The report was of a case of cancer of the stomach (scirrhus) in a boy of nineteen years, with extensive infiltration of the stomach and early obstruction of the cardiac orifice. Metastasis in the peritoneum and pleura with fatty ascites had occurred, followed by effusion in the pleural cavities, first left, then right. In the various effusions were cells which, besides containing fatty granules and vacuoles, showed in a large proportion karyokinetic figures, both typical and atypical. After a reference to the literature, a comparison was made with the findings in other effusions in serous cavities, tending to give to such cells a certain diagnostic value.

Dr. Simon Flexner of Baltimore said that he had performed an antopsy on the body of a young person at the Johns Hopkins Hospital, in which there was a large tumor of the mesentery. The cells of this tumor were so remarkable that he called special attention to them, and it was said that a diagnosis of carcinoma might be made from these cells alone. He worked the case up further, and demonstrated that it was a case of primary tuberculosis of the peritoneal glands.

THE INFLAMMATION OF THE COLON.

By **Dr. Francis Delafield** of New York.

Dr. Delafield read a brief abstract of an exhaustive paper with this title, illustrating it with an extensive series of very large and beautiful photomicrographs. He dealt simply with the forms of inflammation of the colon to be found in and near New York. He divided the disease into (1) A colitis without structural changes in the colon, of which the prognosis is good except in children, and which can be successfully treated in a variety of ways. (2) A colitis with purulent infiltration of the connective-tissue coat, which is regularly fatal, and for which there is no satisfactory treatment. (3) A colitis with exudation, productive of new tissue and necrosis, the inflammation beginning in the glandular coat, which has a disposition to continue for a long time, is sometimes fatal, and is difficult to treat satisfactorily. (4) A colitis with exudation, the formation of false membranes and necrosis, of which the prognosis is serious, and for which the best treatment is the administration of large doses of ipecac and the irrigation of the rectum. (5) A colitis caused by the ameba coli, characterized by necrosis combined with a variety of inflammatory changes, and often associated with similar changes in the liver, of which the prognosis is serious, and for which the best treatment is the administration of large doses of ipecac and the irrigation of the rectum.

He said, as regards the treatment of these different forms of colitis, it seems to me that the first thing to determine is whether the inflammation is confined to the lower end of the colon, or extends higher up. The second thing to determine is whether the inflammation is or is not accompanied by necrosis of portions of the wall of the colon. If the inflammation is confined to the lower end of the colon it can be treated by irrigation alone. If it is confined to the upper two-thirds of the colon it can be treated by drugs alone. If it involves the whole length of the colon both drugs and irrigations are necessary. An irrigation for an adult should consist of as much as two quarts of fluid, and the fluid must run in and out freely. If the colitis is acute and without necrosis, the best fluid is an infusion of flaxseed. If it is a colitis with necrosis, solutions of corrosive sublimate, chlorid of zinc, and formalin have given me the best results. If the inflammation involves the upper part of the colon and is without necrosis, rest in bed, a milk diet, and the preparations of opium and of bismuth are usually all that are necessary. But if it is a colitis with necrosis, ipecac in large doses, castor-oil in small doses, nitrate of silver, salol, and naphthalin are the most useful drugs.

The remaining three papers were read by title.

(Continued on page 614.)

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty Second Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

First Day—May 4th.

The President, **James R. Chadwick, M.D.**, in the Chair.

Dr. A. F. A. King of Washington read a brief address of welcome, which was happily worded and to the point.

Dr. Bache McE. Emmett of New York read a paper, entitled

MULTIPLE MYOMATA IN THE ABDOMINAL CAVITY.

The tumors referred to belong to that class of myomata known as leiomyomata or myoma levicellulare, those formed by unstriped muscular fiber. They generally spring from the uterus, but are occasionally found in other organs. It was formerly believed that these growths were caused by "irritation" or "inflammation," but this explanation is hardly sufficient. They develop most frequently in the uterus, as this organ is made up almost entirely of unstriped muscular tissue, and although they are supposed to be permanent, they increase or diminish in size and take on many changes in structure. In the uterus, this is probably due to the contractility of the tissue, to pressure, or to some change in the blood supply; as, for example, when the menopause is established. Although they show little tendency to malignancy, they often degenerate into carcinoma or into spindle or round-celled sarcoma. The symptoms are usually those due to pressure on neighboring viscera.

The author reported an interesting case in which several of these tumors were found in the abdominal cavity of a woman twenty-eight years of age, each having a pedicle of omental tissue and no uterine attachment whatever. The patient was first operated upon in 1894, when a large mass, adherent to omentum and intestines, and attached to the fifth lumbar vertebra, was removed. The left ovary was found to be cystic and was also removed with the tube. On microscopic examination, the tumor proved to be a myofibroma, and the pathologist expressed the opinion that it had at one time been attached to the uterus. The author considered the growth retroperitoneal, as it had raised up the peritoneum and ureter. During the removal of the tumor, the ureter was accidentally severed, and a ureteral anastomosis made to close it. The case was carefully watched, as it was feared obstruction to the outflow of urine might follow. The patient did well and returned home in the fourth week. Seventeen months later she was delivered of a boy by means of forceps. Soon after this a large, hard mass was found on the left side which felt like an ovarian cyst. There was no pain, and it was thought to be a recurrence of the fibroid. Four months later another tumor developed on the right side, both being movable.

A second operation was performed two years after the first, and upon opening the abdominal cavity a long nodular, lobulated mass was found upon the uterus, apparently part of it, and composed of several tumors. On exploring with the hand in the pelvis, it was found that the growths were not connected with the uterus, but were attached to the omentum and surrounded by adherent small intestine. Each tumor had a pedicle of omental tissue which contained blood-vessels. In all, seven of these growths were removed, and the last, which so much resembled a kidney that it was thought to be one until exploration proved otherwise, was attached to the ureteral anastomosis which had been made two years previously. The right ovary was cystic, and was removed together with the tube. Three small nodules were noticed on the left side of the uterus, but these were left untouched. Soon after this operation, a swelling developed at the site of the original tumor—the fifth lumbar vertebra, and rapidly increased in size. This was accompanied by a rise of temperature which reached as high as 104° F., and it was feared the abdomen would have to be again opened. However, she soon began to improve and returned to her home in a few weeks. The tumor is still there and is probably growing, but the patient is doing well and has gained strength and weight.

DR. CHARLES P. NOBLE of Philadelphia read a paper, entitled

THE HISTORY AND PRESENT STATUS OF HYSTERECTOMY FOR FIBROID TUMORS OF THE UTERUS.

The author gave a *résumé* of the development of hysterectomy for fibroid tumors of the uterus, and referred especially to the part taken in it by American surgery and paid a glowing tribute to the operators of this country. He described the different methods of performing the operation: (1) stitching the stump in the abdominal wound; (2) covering it with flaps of peritoneum and dropping it back in the peritoneal cavity, and (3) total extirpation. The following conclusions were drawn:

Surgery is indebted to America for ovariotomy and for hysterectomy for fibroids. Ovariotomy was originated by McDowell in 1839, and hysterectomy must be considered as an outgrowth from it, the first fibroid tumor having been operated upon under a diagnosis of ovarian tumor. The first hysterectomy for fibroid tumor, deliberately undertaken, was performed by Kimball in 1853.

The type of hysterectomy in America has been supravaginal amputation. This method was adopted by Kimball and by Burnham in 1853. Many surgeons of all countries have worked in this field, notably Schroeder, but in the evolution of the operation, the steps in the technic which have rendered it simple and safe have been originated by other American surgeons. These steps are notably:

1. The retroperitoneal treatment of the stump—Emmet, 1884; Eastman, 1887; Dudley and Goffe, 1890.
2. The ligation of the trunks of the ovarian and the uterine arteries in their course through the broad ligaments—Stimson, 1889; Baer, 1892.
3. Amputation through the cervix well below the internal os, and the omission of constricting ligatures in the tissues of the cervix—Baer, 1892. The substitution of a few catgut sutures to close the cervix and prevent secondary infection from the vagina through the cervical canal.
4. The origination of a systematic technic for the removal of intraligamentous fibroid tumors—Pryor, 1894; Kelly, 1896.

The mortality of fibroid tumors is greater than is usually stated. It much exceeds the mortality of operations for the cure of the disease.

The mortality of supravaginal amputation for fibroid tumors of the uterus at the present time is about five per cent.

The mortality of total hysterectomy is greatly increased by the traditional policy of delay in advising operation for fibroid tumors, which still influences both practitioners and surgeons.

Early operation for fibroid tumors should be urged upon the basis of genuine conservatism as contrasted with spurious conservatism. Early operation insures a low mortality. It permits the substitution of myomectomy for hysterectomy in women of child-bearing age in a larger percentage of cases than is possible with tumors of large size. It conserves the life and the health of the patient, and, when myomectomy can be performed, restores her sexual organs to functional integrity.

The policy of delay, or spurious conservatism, conserves only the continued growth of the tumor. It entails upon patients years of invalidism or semi-invalidism, and subjects them to much greater risks than those of early operation. Finally, many of those who have suffered for years in the hope of relief without operation are obliged to submit to hysterectomy when their chances for recovery are much less than had the operation been done early.

The next advance in the treatment of fibroid tumors will be the acceptance of early operation with the definite purpose of substituting myomectomy for hysterectomy in women of child-bearing age, in cases having only a small number of fibroid nodules.

DISCUSSION.

DR. R. S. SUTTON of Pittsburg said the surgical treatment of fibroid tumors of the uterus has been a progressive evolution since the days of Kimball. He did not think, however, that every woman with a fibroid should be operated upon. The late Thomas Keith had made the statement that only ten per cent. of all women so affected died as a result of the tumor when it was left untreated, and that, to make the operation justifiable, the mortality following it should be less than this. The speaker advocated conservative measures in those cases where the tumor caused no symptoms. Operations are dangerous, even in the hands of experienced men, and he thought they should be resorted to only when absolutely necessary.

DR. ARTHUR W. JOHNSTONE of Cincinnati considered the treatment of these cases one of the most important questions in modern surgery. His views on the subject, like those of his teacher, Lawson Tait, who, by the way, was considered very radical, were conservative. The speaker had seen 500 cases of uterine fibroid and had operated on only 100 of them. He occasionally removed the appendages to arrest the growth of a fibroid, and had never lost a case and never seen one which was not benefited by the operation. Some of these tumors are of a lymphoid nature, and in these cases the menopause, whether naturally or artificially produced, has no effect, and nothing but a radical operation will cure them. Such cases, however, are rare. When a case demanded it, he was in the habit of performing hysterectomy, and whenever possible, he left the cervix and never tried to close it, because there was sure to be a certain amount of drainage. Like the preceding speaker, he was in favor of conservative treatment, and thought many women were operated upon who did not require such radical treatment.

DR. B. F. BAER of Philadelphia was also an advocate of conservative treatment, but believed that conservatism in these cases is in the direction of radical surgery. He sometimes did myomectomy, but preferred supravaginal amputation of the uterus. This was the position he held in 1892, and he had had a great deal of experience since then. It is not conservatism to decry an operation which has been successful, and has saved so many lives and so much suffering. He did not believe a fibroid of the uterus could exist and not produce suffering at some time or other, and his experience had led him to advise against waiting for the menopause for relief. It is only exceptionally that the menopause has a beneficial effect, and in 95 out of 100 of these cases he was ready to advise operation.

(To be continued.)

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Continued from page 600.)

SECOND DAY—MAY 5TH.

The attendance at the second session of the general congress was fully three times as great as that of the first day. The session was held under the auspices of the Association of American Physicians, the American Physiological Society, and the American Pediatric Society, **DR. WILLIAM H. WELCH** of Baltimore presiding. The subject for discussion was

INTERNAL SECRETIONS CONSIDERED IN THEIR PHYSIOLOGIC, PATHOLOGIC, AND CLINICAL ASPECTS.

The first paper, on the

PHYSIOLOGY OF THE INTERNAL SECRETIONS,

was read by **DR. WILLIAM H. HOWELL** of Baltimore. (Dr. Howell's paper will appear in a succeeding issue of the NEWS.)

Following this, **DR. RUSSELL H. CHITTENDEN** of New Haven, Conn., read a paper on

INTERNAL SECRETIONS CONSIDERED FROM A CHEMICO-PHYSIOLOGIC STANDPOINT.

The essayist desired to emphasize the fact that the symptoms which follow the simple removal of a physiologically active gland from the body result solely from the loss of the gland. When attention was first called to the possibility of producing typical myxedema in monkeys by the removal of the thyroid gland, there was a tendency to explain the phenomena as resulting from an injury of the sympathetic or other nerves of the neck rather than to admit even the possibility of a general or limited disturbance of the metabolism of the body through chemical changes associated with the removal of the gland. It was not until the experiments of Murray made clear the fact that the effects resulting from the removal of the thyroid in man could be overcome, in part at least, by the administration of the gland substance, that scientific investigation took the proper turn, and a full realization of the possible importance of the so-called ductless glands and their internal secretions began to dawn upon the mind. To-day we recognize their functional activity as a necessary element to the welfare of the body.

The literature of the subject was then carefully reviewed. The thyroid gland manufactures one specific substance of marked physiologic power—the so-called colloid of Hutchinson, a body which, although containing phosphorus, is not a nucleoproteid, neither is it allied to mucin. It it peculiar in that it contains iodin. This body, when acted upon by the gastric juice, or by boiling acid, is split into a proteid and a non-proteid part, the latter containing all of the phosphorus and a larger part of the iodin of the original colloid. According to Hutchinson, both parts of the colloid are physiologically active, but the non-proteid part, the iodothyrin of Bauman, is unquestionably far more active than the proteid part of the original molecule. This substance is apparently the physiologic equivalent of the thyroid gland.

For the sake of completeness, the speaker made brief reference to Notkin, whose theories are now known to rest upon a false foundation.

Concerning the other internal secretions, DR. CHITTENDEN had but little to say, owing chiefly to the fact that there is little chemico-physiologic knowledge at our disposal. In reference to the adrenals, however, he stated that there is some evidence of the existence of two physiologic substances, one insoluble in ninety per cent. alcohol—possible the sphygmogenin of Fränkel—which increases blood-pressure; the other freely soluble in alcohol, which causes paralysis of the heart and muscles and death by suffocation. In this connection he called attention to the fact that Oliver and Schäfer have shown that the active principle (or principles) is non-volatile and that its activity is not destroyed by mineral acids or gastric digestion, while alkalies greatly diminish it. According to Marino-Zuco, the toxic action is due to the presence of neurin-glycero-phosphate. There are also some grounds for believing a benzo-catechin-like body to be present, which may exert some physiologic action.

Lastly, in extracts of the testis, a peculiar nitrogenous body, free from oxygen, has been detected, known as spermin, and which is claimed by Poehl to have a marked influence upon metabolism and to act as a true physiologic stimulus. Further discussion of these points, however, at the present time, would have little value.

The next paper,

THE INTERNAL SECRETORY ACTIVITY OF GLANDS IN RELATION TO THE PATHOLOGICAL ANATOMY OF SUNDRY MORBID CONDITIONS (SEE PAGE 581),

was read by DR. J. GEORGE ADAMI of Montreal.

DR. FRANCIS P. KINNICUTT of New York opened the discussion by reading a paper on the

CLINICAL ASPECT OF THE INTERNAL SECRETIONS.

He called especial attention to the beneficial effects which have been obtained from the administration of thyroid extract in myxedema. It has been shown that the patients can be cured after as long a time as even fourteen years, but that the maintenance of health can be secured only by a continuation of the remedy during the rest of the life of the individual. In support of these statements, reference was made at some length to the remarkable results reported with the treatment by Murphy, in that patients were not only restored to apparent health, but were fitted for such arduous tasks as mountain climbing. Cases were also reported which had come under the observation of the speaker. He showed that not only could myxedema be cured, but that the fearful lack of skeletal development could be overcome in these cases, and the mental condition be very materially improved at the same time by administration of thyroid extracts. The radiograph has been used to determine skeletal growth with reference to prognosis in these cases. It is noteworthy also that a relative softening of bone has been observed to follow what was believed to be an over-dosage with thyroid extract. It is justifiable to conclude that the treatment with thyroid extract holds forth every promise of a child's development, in congenital cases, when the treatment is commenced early and persistently continued.

Goiter.—Turning to the other morbid conditions, the speaker remarked that the benefit obtained from the administration of thyroid extract in goiter has not been satisfactorily explained. The benefit consists in the retrogression of the goiter, through recession of the hyperplastic tissue. Kocher attributes the benefit to a shrinkage of the parenchymatous tissue. Complete disappearance of the tumor has been rarely observed. Reports of permanent cures have not been sufficiently numerous to allow of positive statements. Recurrence after discontinuence of the treatment has been observed, and it is probable that a prolongation of the treatment is also necessary in this condition.

The speaker then referred to the literature of the subject. From it he concluded that varying, although almost uniformly beneficial effects, were obtained from thyroid treatment in all forms of goiter. Finally, he remarked that thyroid treatment has been found to be beneficial in quite a number of conditions in which perversion of the thyroid function has not been observed. The use of thyroid extracts in various forms of insanity was doubtless based upon the power of the agent to increase metabolism. Bruce believes that its action under these circumstances is a complex one. First, the fever which is induced is often beneficial; and second, the thyroid apparently supplies something which is deficient in the systems of these patients. Allan Starr finds its effects especially beneficial in cases of acute mania occurring about the climacteric period,

Obesity.—The literature of this subject is already very voluminous and the results have been generally favorable. There is a decided increase in the excretion of nitogen following administration of thyroid extracts as compared with that received with the food. It has been shown that there also is an albuminoid waste which should be compensated for by a regulation of the diet. Benefit is also seen in cases due to over indulgence. Loss of weight is greatest during the first days of treatment, varying during subsequent days without apparent cause. Only exceptionally has improvement been long continued.

Cutaneous Diseases.—The expectations from this treatment in cutaneous affections have not been realized. Only in psoriasis has any marked benefit been derived from it, and even in this affection the results have not been as great as were anticipated.

The Adrenals.—Modern literature strongly indicates that the adrenals are functionally active glands. One view is that the function is excretory; the other, that it is secretory. The conclusion of various observers seems to be that a substance is produced which is capable of neutralizing the effects of certain products of metabolism, or of bacterial activity. The result of the reosorption of the secretion of the adrenals is the stimulation of the vagi and other nerves of the sympathetic system, thus stimulating respiration. Other observers have concluded that the action is directly on the muscles, without the intervention of nervous mechanism. The employment of adrenal extract has been advocated in cases in which the function of these glands has been supposed to be deficient. In Addison's disease, for example, the speaker had seen marked benefit from this treatment. One case of Graves' disease has been reported in which the treatment was beneficial. In some of the cases of Addison's disease in which benefit had been obtained relapse and death afterward occurs. In cases of atrophy of these glands he thought it is apparent that most benefit would be obtained from treatment with extracts of the glands.

He then made brief reference to the treatment with extracts of the thymus gland and pituitary body, and reported some experiments which he had made in his hospital wards in cases of apyretic phthisis. His conclusion is that it is not a stimulant of nutritive processes in general. Only a few symptoms were ameliorated. He suggested that the stimulation of the heart muscle, or the walls of the blood-vessels which had been observed after the administration of the extracts of adrenals indicated their use in cases in which the functions of these organs are impaired. Their action is believed to be beneficial in cases of heart failure, but further study is necessary to determine their true therapeutic value. The action is not unfavorably influenced by gastric digestion, and comparatively large doses may be administered, as much as 45 grains daily, for very long periods without injurious effects.

DR. JAMES J. PUTNAM of Boston then read a paper in continuance of the discussion. He took a somewhat less extensive view of the subject than his predecessors, holding that the only affection which we can as yet positively assert to be of thyroid origin is the myxedema cachexia. It is even doubted whether true endemic cretinism should be included as a thyroid affection. He then described the peculiarities which characterize the cretin. Intermediate forms of the disease occur, he said, and the differences of type are claimed to be due to the fact that the cretin is degenerate as well as myxedematous, in consequence of morbid in-breeding. At all events, it is noteworthy that true cretinism is not benefited by thyroid treatment to anything like the same extent as so-called sporadic cretinism.

It is still a question how far in the direction of what is ordinarily called "health" we ought to extend our conception of myxedema, and it is probable that some of the changes commonly attributed to old age are a result of lack of thyroid secretion. Horsley suggests that some of the symptoms of Graves' disease, especially the dyspnea, may be due to a lack of certain constituents of this secretion. When one considers that the structure of the thyroid does not provide for the pouring out of a definite quantity of secretion, that half the gland may be cut away, and that at autopsies it is often found atrophied or hypertrophied, the conviction forces itself upon the mind that an exact balance between thyroidal and antithyroidal substances and tendencies cannot at every given moment exist, and that leanings toward thyroidal excess or of thyroidal deficiency must be present during what seem to be normal states.

Reference was then made to the discussion of the subject of obesity in its relation to thyroid treatment at the Congress of German Physicians at Wiesbaden last summer, when Spitzer pointed out the fact that a sharp distinction should be made between the obesity which is due to food, mode of life, etc., and that which is due to metabolic activity. Ewald has not, however, found this distinction tenable in practice.

Referring to the complex series of symptoms which result from castration, he stated that it is conceivable that eunuchism might be benefited by following the line of treatment for myxedema and giving testicular extracts, and he was surprised that it had not been tried. It would, however, be hard to believe that the same treatment would work so satisfactorily in infantilism.

The Congress then adjourned to the library of the Army Medical Museum to participate in the ceremonies of unveiling the statue erected by the American Surgical Association and the Alumni Association of the Jefferson Medical College in honor of the late Professor Samuel D. Gross.

The exercises were conducted by the American Surgical Association, Dr. J. Collins Warren of Boston, chairman, acting as master of ceremonies. Prayer was first offered by the Rev. B. L. Whitman, President of the Columbian University.

The presentation of the statue to the United States Government was then made in an address by DR. CLAUDIUS H. MASTIN of Mobile, Ala. He first referred briefly to the high character of the Association which presented the statue. They had come together to honor one of their distinguished members who is now dead, and to show their appreciation of what he had done. His life and character were such as are worthy of the emulation of everyone. Born of German parentage, he had acquired those sterling qualities of head and heart which characterize the race from which he sprang—qualities which are essential to great deeds and invaluable in the contest for the survival of the fittest. We find him a poor boy, without the prestige of name or the influence of family or fortune, of studious habits, ambitious, struggling and toiling along in the paths of a young practitioner of medicine. We know how he surmounted obstacle after obstacle. Adversity came and was thrown aside. Nothing daunted, he pressed on to a higher career. Ere he had reached the meridian of life he had become a master in surgery. Endowed by Nature with the strong intellect which he had fully cultivated, he dedicated it to the relief of human suffering and thereby lengthened the span of human life. He reached the highest position ever attained by an American physician. He was fearless, and withal, without arrogance, he was charitable. He was crowned with the highest degrees of almost every foreign university. He had added to literature by exhaustive research. A voluminous writer, he was the author of many books which, by translation into various languages, have become standard the world over, wherever the art of surgery is known, or wherever Hippocratic medicine is practised. "Full of years, full of honor, beloved at home and abroad, he rounded up his great career and rested from his labors on the 6th day of May, 1884. Such is the outline of a life which in the prodigality of Nature, was not intended for any age, but for all time, a life of which we can truly say '*Finis coronat opus.*'"

The speaker then referred briefly to the origin, work, and completion of the movement which had terminated in this presentation of the statue to the people of the United States.

BRIGADIER-GENERAL GEORGE M. STERNBERG, Surgeon-General U. S. A., in accepting the statue for the Government, remarked that it was a pleasing duty which had been conferred upon him to accept, in the name of the people of the United States, this mark of honor and respect bestowed upon the memory of one who had been so honored and so beloved. He had not come to pronounce a eulogy upon the distinguished Gross: this honor had been conferred upon another better able and qualified by long association with the late distinguished surgeon for the task. He referred to the vast contributions which he had made to the literature of surgery, and said that it was fitting that the statue had been placed so near to the Army Medical Museum, in the library of which so much of his literary work had been done. After dwelling upon the advances that have been made in surgical practice in recent years, and the pleasure that a knowledge of these advances would have given Dr. Gross, the speaker said that he felt justified in conveying to the donors of the statue the thanks of the entire medical profession.

DR. WILLIAM W. KEEN of Philadelphia, successor to the Chair of Surgery in Jefferson Medical College, then delivered the address of the occasion, which consisted in a brief narration of the life, history, and achievements of Professor Gross. (See page 591.)

AMERICAN SURGICAL ASSOCIATION.

(Continued from page 603.)

SECOND DAY—MAY 5TH.

DR. DEFOREST WILLARD of Philadelphia showed and explained a large number of photographs.

DR. EDMOND SOUCHON of New Orleans read a paper, entitled

THE OPERATIVE TREATMENT OF IRREDUCIBLE DISLOCATIONS OF THE SHOULDER, RECENT OR OLD, SIMPLE OR COMPLICATED.

The speaker considered all the forms and varieties of irreducible dislocation of the shoulder, and studied to determine the operation which should be performed for each variety, the difficulties and complications after the operation, the immediate results, the remote results, and formulated conclusions as to the advantages or disadvantages of each. The study is based on one hundred and forty cases operated upon. The profound silence of the text-books and also of special books on dislocations in regard to this most important subject renders this study most imperative and timely.

All irreducible dislocations, recent, simple, or complicated with fracture, that were operated upon by reduction or resection have given good results, with one exception, in which death occurred, and did not seem to be due to the operation alone, but to a complication of unusually severe shock.

Irreducible dislocations, old, simple, and forward, operated upon by resection through an anterior incision, are the most frequent, fifty-six cases against thirty-three by arthrotomy and reduction. Remote results show a great mortality percentage in resections from injuries to the vessels, but this is avoidable with special care. The fatalities in reduction have been due to sepsis, now preventable. The disadvantage of reductions is necrosis, calling later for sequestratomies and resections. This is probably due to the greater dissections and denudations of the head and surgical neck necessary for reduction than to simple resection of the head. Reduction is the more desirable operation of the two because it preserves the head and all the movements depending thereupon, but the necrotic consequences are serious drawbacks, as is also the ankylosis which sometimes follows the reduction. It should not be resorted to unless it can be easily accomplished without too extensive dissections although it may be necessary to use hooks, levers, and some curetting of the cup, as the cases reported show. The duration of the dislocation is immaterial; it is the condition of the parts that is all important. Recent irreducible dislocations have been as much, if not more, troublesome than dislocations of long standing.

The anterior incision is the route of selection in all forward dislocations; almost all forward cases operated upon by the axillary route and the posterior incision have been unfavorable. Cases reported as operated upon by subcutaneous section of fibrous bands, of tendons, of muscles, and by osteotomy, have given good results, but their number is as yet limited. It seems extraordinary that surgeons have not employed these methods oftener; perhaps they have, but, having failed, have not reported the cases. Considering the extent and the density of the tissues binding down the head and surgical neck to the surrounding parts, reported by operators, it is a wonder that these methods should succeed except in unusually loose cases.

Irreducible dislocations, old and downward, four in number, have all been treated by the axillary incision with resection, *i. e.*, removal of the fractured head found more or less loose in the axilla, with favorable termination. In one case, however, the head was "pegged back" and reduced, with a good result. One downward dislocation (Després') was treated by osteoclasis, but it was a failure, no false joint forming. Yet there are cases on record of forward dislocation in which the bone was fractured near the head or through the surgical neck during the efforts at reduction, and which yielded a fair result.

Irreducible dislocations, old and backward, in the adult, have been reported twice. They were operated upon by resection, with a very ordinary result.

Irreducible dislocations, old, upward, and operated upon, have not been recorded.

Irreducible dislocations, congenital, have been operated upon several times; they were old, backward dislocations. Two cases were operated upon by reduction; one patient died, the other had to have sequestra removed, but eventually recovered. Three cases were operated upon by resection, two with good results; in the third the result is not given.

Irreducible old dislocations in young subjects or in old subjects were duly considered by the author; also, old dislocations double, *i. e.*, of both shoulders; as well as spontaneous or pathologic and paralytic irreducible old dislocations.

The forms and varieties due to complications accompanying irreducible old dislocations were fully treated and also the forms and varieties due to relapses or recurrences and to the sequels of the operations performed for irreducible dislocations, old, simple, or complicated.

DISCUSSION.

DR. J. EWING MEARS of Philadelphia, referring to Dr. Souchon's paper, advised that the word "irreducible" should be dropped and the word "unreduced" substituted. The word irreducible is a term which can be applied when efforts at reduction are limited to manipulation, while the word unreduced would refer to dislocations which cannot be reduced even by operative procedures. He suggested that some rule should be laid down as to when a dislocation should be considered acute and when chronic. In all cases of recent dislocation of the shoulder which cannot be reduced by manipulation, and operation is considered advisable, he recommended an incision through the deltoid muscle as being probably the best method. He considered that disability and pain were the two indications for operative interference in old dislocations, and mentioned that he had seen cases of old unreduced dislocations in which as much freedom of movement had been accomplished as was usual in excision of the head of the bone without any bad effects. In some old cases of dislocation he considered massage as being advisable before resorting to operation. With regard to the relief of pain in these cases, he thought any operation that would relieve pressure should be performed, and that that was a question that could hardly be discussed. He referred to an operation performed by himself in 1886 in which he did a subcutaneous section of the neck of the humerus, in which the object was to form a false joint. Although the operation was successful as far as the relief of pain was concerned, upon the death of the patient one year later, examination showed that a false joint had not been formed, but union had taken place at an obtuse angle in such a manner as to pull the head of the bone off the axillary plexus. The tissues around the joint had been stretched to such an extent as to permit the head of the bone to return almost to the glenoid cavity.

DR. JOSEPH RANSOHOFF of Cincinnati considered that operative treatment in uncomplicated dislocations of the shoulder of recent occurrence were so readily reducible under anesthesia by manipulation, that operative treatment very rarely came into the question, and that unreduced dislocations of long standing, as far as treatment is concerned, must be entirely determined by the degree of disability entailed. Where this is slight the patient is enabled to gain a livelihood, and pressure symptoms are absent, particularly if the dislocation is one of more than two or three months' standing, the advisability of operative interference must be questioned. But pressure upon the vascular, or nerve trunks was a positive indication for operative interference. The operations suggested and practised for irreducible dislocation of the shoulder are (*a*) subcutaneous division of the adhesions, (*b*) subcutaneous osteotomy of the neck of the humerus, (*c*) arthrotomy, and (*d*) resection. The French surgeons alone advocate the first-named; however, the last two are most frequently indicated. In old cases, even where reduction is accomplished, there remains where the head had been situated a large cavity bounded by firm fibrous walls and often lined with an imperfect serosa which closes with difficulty and affords a ready nidus for infection. The earlier interference is practised the better are the final results. The immediate fatality following arthrotomy is very considerable. The present status of the question of operative interference in shoulder luxations may be summarized as follows:

(*a*) Immediate operative interference is indicated when the ordinary methods by manipulation under anesthesia have failed. (*b*) In irreducible dislocations, operations should not be delayed until irremediable changes have taken place in the capsule and about the humeral head. In comparatively recent cases arthrotomy offers the best results. (*c*) In old-standing cases the conditions found must determine the choice between arthrotomy and resection. (*d*) In unrecognized dislocations of long standing, a year or over, only grave compression symptoms should be recognized as indications for interference. (*e*) Special attention should be given to the prevention of sepsis, since in a very large proportion of cases recorded sepsis has been either the cause of death, or by the destruction of the humeral head, or obliteration of the joint cavity, has frustrated the very object of the operation.

DR. J. J. OWENS of Chicago stated that his experience with cases of this kind was limited to three, the first one of which was of the subcoracoid variety; in this, attempts at reduction were unsuccessful, and it was necessary to cut down through the deltoid muscle into the joint. Caries, suppuration, and necrosis set in, and finally resection had to be done. Since this case, he had seen one which proved to be a dislocation of seven or eight-weeks' standing, although it was said to be a fracture. In this instance an incision was made through the deltoid muscle, which was enlarged with a probe-pointed bistoury, but it was still impossible to reduce it. The subscapular tendon was then divided, and although nothing could be found which seemed to be holding the bone, it was still impossible to reduce it, and a resection had to be done, which was followed by excellent results. The third case was one of dislocation, which had been overlooked and mistaken for a fracture, and in this case also manipulation failed. In performing Kocher's method of rotation of the arm outward, the upper end of the bone gave way. Its position was improved at once, and the pain finally disappeared. In order to prevent union, and to make a false joint, if possible, the bone was moved every day. Movement increased, and considerable usefulness was secured, so that the accidental result proved satisfactory.

DR. JOHN B. ROBERTS of Philadelphia referred to one case in which, in attempting reduction, much bruising of the soft parts resulted, and it was necessary to postpone operative interference until this condition improved. Later he discovered that he had put the head of the bone on the brachial plexus, so that the patient was worse off than ever, and resection was necessary. The patient succumbed from shock and hemorrhage within twenty hours.

DR. L. MCLANE TIFFANY of Baltimore saw no reason why cases of dislocation of the shoulder joint should be considered in a different manner from those of any other joint, and considered free opening a proper procedure. As to the time when a joint should be considered irreducible, no hard and fast rule could be laid down as the variations are too great. After the head of a bone is firmly fixed in its abnormal position, resection is the best thing to do, as a painless and useful arm will invariably result.

DR. SOUCHON closed the discussion of the paper, and referred to the fact that even Dr. Kocher had fractured cases in his attempts to reduce dislocations, and one patient had died. He spoke against waiting too long before operating on these cases on account of the adhesions which so often occur. He considered the deltoid muscle the all-important factor in the operation, and particularly on account of the division of the filaments of the circumflex nerve and the resulting paralysis. He laid great stress upon the after-treatment, and particularly as to when it should be commenced, stating that this must be decided according to the case.

DR. E. H. BRADFORD of Boston read a paper on

TENDON ANASTOMOSIS.

Referring to the transplantation of tendons and tenoplastic surgery, he spoke of the good results which have followed the transference of one of the perinei muscles from one side of the limb and attaching it to a paralyzed muscle on the opposite side to correct a deformity of the foot resulting from such paralysis. He also referred to the union of the anterior tibial and extensor longus pollicis muscles, to shortening the extensor tendons of the foot and also of the Achilles tendon, as well as transplantation of the sartorius tendon. In cases of spastic paralysis, he advocated lengthening of tendons and muscular fasciæ in the popliteal space, in the groin, in the forearm, and in the hand. He also showed diagramatically a method of splitting the patella, of shortening a lengthened ligamentum patella, and shortening a relaxed capsule. He stated that before transplanting a muscle one should prove by electricity that the muscle itself is alive and healthy, and strong enough to do the work. He stated that excellent results have followed these operations, and demonstrated with photographs and drawings cases before and after operation.

DR. JOHN B. ROBERTS of Philadelphia referred to a case in which paralysis of the extensor of the fingers existed, and in which a laceration of the common extensor was found. Upon attaching the piece of tendon of this muscle to the thumb, the hand was rendered practically as good as ever.

DR. DEFOREST WILLARD of Philadelphia stated that in a number of cases in which he had employed similar methods much improvement had followed.

DR. BRADFORD closed the discussion by referring to a case of Dr. Dawbarn's in which the insertion of the ligamentum patella was transferred by chiseling off the tubercle to which it is attached, crushing a portion of the tibia, and inserting the tubercle there.

DR. JOHN B. ROBERTS of Philadelphia read a paper, entitled

THE SURGICAL TREATMENT OF SUPPURATIVE PERICARDITIS.

The author advocated, as he had since 1876, the treatment of pericardial effusions in the same manner as pleural effusions, and stated that parcentesis was insufficient to cure suppurative pericarditis. Incision and drainage were essential and should be adopted as soon as the diagnosis of pus in the pericardium was made. The diagnosis of the purulent character of the effusion was only determinable by exploratory puncture. This should be done at the upper part of the left xiphoid fossa close to the top of the angle between the seventh cartilage and the xiphoid cartilage. Pericardiotomy should then be done after resection of the fourth and fifth costal cartilage in the manner described by the author. The operation was believed to be novel in some of its details, though others have recommended and operated upon by various forms of resection. This method was devised to avoid injury of the left pleura, which is nearly always a complication in the ordinary methods of puncturing or incising the pericardium. As a rule, empyema is liable to occur as a sequel of pericardio-puncture or incision in suppurative pericarditis. The prognosis is good in pericardiotomy for pyopericardium. In a table of twenty-six collected cases, ten recoveries and sixteen deaths were shown. This gave a percentage of recovery of 38.44 per cent. Of the fatal cases, at least nine were septic, and all the others which died had complicating lesions, such as pleuritis, pulmonary, cardiac, or renal lesions. The operation devised by Dr. Roberts consisted in raising a trap-door of the fourth and fifth costal cartilages and connecting soft parts and using the tissues of the third interspace as a hinge. The internal mammary vessels and left pleura are thus exposed and pushed to the left.

DR. CHARLES B. PORTER of Boston discussed this paper and gave the history of one case which was operated on in a manner similar to that recommended by Dr. Roberts. The result in this case was that after convalescence was established the patient was in excellent health and was able to ride a bicycle a considerable distance without fatigue. With regard to the indications for the operation, it may be said with confidence that the percentage of recoveries after its performance warrants the statement that it is indicated in all cases of purulent pericarditis. The author then referred at some length to the surgical anatomy of the pericardium and said that the ideal operation was as far as possible (1) to avoid opening the pleural cavity, (2) to open the pericardium opposite the point where drainage will remain good after the sac has contracted, and (3) to secure permanent and free drainage. He then detailed the steps of the operation and referred to a number of cases of reported recovery from purulent pericarditis treated by incision and drainage. A number of charts and diagrams accompanied the paper.

Dr. J. McFadden Gaston of Atlanta, Ga., discussed this paper and stated that discussion on this subject have laterly inclined to more vigorous measures of internal treatment before using any means of mechanical evacuation. The conditions were more urgent in pericardial effusions than in pleural effusions. It may be said that aspiration is not applicable to purulent collections in the pericardium and should be limited to serous effusions. The author then referred to a number of medical publications in which references were made to this subject and stated that the only means available for testing the character of the contents of the pericardium is the aspirator or the hypodermic syringe. If serum is found, it should be evacuated and medication begun with such agents as have been found most efficacious in serous pleural effusions, but if a purulent collection is already present, the case required incision and drainage without delay.

Dr. Roberts closed the discussion by stating that he would add the cases referred to by the gentlemen to the statistics in his paper.

Dr. S. H. Weeks of Portland, Me., read a paper, entitled

REPORT OF A CASE OF REMOVAL OF THE GASSERIAN GANGLION.

The author gave the history of the case as related by the patient himself, and the only apparent cause for the neuralgia seemed to be excessive mental work. After describing at length the details of the operation, the speaker stated that the only marked symptom remaining is inability to call up or speak certain names. There seems to be a limited amount of aphasia, which has been present from the first, but which is gradually disappearing.

Dr. G. R. Fowler of Brooklyn stated that he knew the patient personally, and could vouch for his intense suffering previous to the operation.

He also reported that the two cases of ligature of the common carotid and of the external carotid, performed to starve the Gasserian ganglion which he reported to the Society last year have remained free from a return of the disease.

THIRD DAY—MAY 6TH.

Dr. Dudley P. Allen of Cleveland, Ohio, read a paper on

THE ORIGIN OF APPENDICITIS.

Dr. L. M. Tiffany of Baltimore read a paper on

INTRACRANIAL SURGERY,

after which the society went into executive session and elected the following officers: President, Dr. S. F. Pewitt, St. Louis, Mo.; Vice-Presidents, Dr. J. McFadden Gaston, Atlanta, Ga., Dr. M. H. Richardson, Boston; Secretary, Dr. H. L. Burrell, Boston; Treasurer, Dr. G. R. Fowler, Brooklyn.

The next meeting of the Association will occur at New Orleans, April 20, 1898.

ASSOCIATION OF AMERICAN PHYSICIANS.

(Continued from page 606.)

SECOND DAY—MAY 5TH.

A CASE OF PANCREATITIS FOLLOWED BY THE FORMATION OF A CYST.

Read by Dr. A. McPhedran of Toronto. A case was detailed in which there was a history of recurrent attacks of colic for about five years, then a sudden effusion into the omental bursa, which was evacuated; after that a large cyst of the pancreas formed. This was opened and drained, and the case recovered with the persistence of a sinus. The cyst was of true pancreatic origin, but contained no pancreatic secretion. Their precise nature is uncertain. The moderation of the attacks of colic consequent upon the formation of the cyst, and their complete relief by the evacution of the cystic contents, pointed to some mechanical irritation caused either by cicatricial contracture or external pressure.

ANGINA PECTORIS; ITS RELATION TO DILATATION OF THE HEART,

was the title of a paper by Dr. J. H. Musser of Philadelphia. Patients who have had an attack or attacks of angina pectoris are relieved of the paroxysms if dilatation of the heart supervenes. Often, if dilatation persists, the patient may live for years and no other paroxysm occur. It seems the pain, as long ago pointed out, is due in large part to the stretching of a tense ventricle from intracardiac pressure. Such stretching is not so likely to occur in dilatation because of "safety-valve action" in the heart. This appears to explain the infrequency of angina in the young; in mitral valvulitis with regurgitation; in women, possibly; and in the occupants of infirmaries and hospitals. In the latter class the vigor of the heart muscle is lessened from lack of food, etc. Certainly it is not because of the absence of atheroma of the coronary arteries, for endarteritis is very prevalent among senile, usually alcoholic, perhaps syphilitic inmates of the hospitals and almshouses.

If the contention is true, the diagnosis, prognosis, and the treatment, tentatively admitted, is influenced as follows: The diagnosis, in that angina-like paroxysms in dilatation of the heart are probably not due to true angina pectoris; the prognosis, in that, if, as rarely happens, an undoubted attack of angina occurs in a case of valvulitis with dilatation, and even failing compensation, the patient on the one hand is not likely to perish from the angina, because of the safety-valve, while, on the other hand, it indicates that there is sufficient strong muscle fiber to insure cardiac recuperation. Further, if a patient subject to attacks of angina presents signs and symptoms of dilatation, the angina will disappear, or at least never be so severe as to terminate fatally.

That the pain is due to intracardiac pressure is more possible because of the presence of dilatation of the heart in angina *sine dolore*. Attention is called to a similar association of pain with increased tension of the globe, in acute glaucoma.

DISCUSSION.

Dr. Wharton Sinkler of Philadelphia questioned the statement of the author that the pain in angina is due to intraventricular pressure, for in pseudo-angina the pain is just as acute as in the organic disease. He gave the history of a case of pseudo-angina in a hysterical girl in which morphia and other drugs failed to give relief.

DR. H. C. WOOD of Philadelphia also questioned the dependence of anginal pain upon intraventricular pressure. In this connection it is interesting to note the effect of nitrite of amyl. As to digitalis in this condition, if there be an insufficiency of the mitral valve there might be intense pain from its administration. It is more likely, he thought, that the pain is due to distention of the auricle. There is another thought suggested. If the theory of Dr. Musser be correct we should be able to relieve the symptoms by the administration of aconite, for it is well known that if we give enough aconite we would do away with intraventricular pressure altogether. The problem is to do away with the pain of the patient without, at the same time, doing away with the patient, and this is best accomplished by the use of digitalis.

DR. EDWARD G. JANEWAY of New York gave the history of the sudden onset of an attack of angina in a man who never before had the disease. The pain, in this case, went down the right arm instead of the left. The man had pericarditis, and Dr. Janeway had suggested that the attack might have been due to the plugging of the coronary artery by a thrombus. The man lived a week after the attack, and his pulse came down to 72 to the minute. He said he felt well enough to get up, and did get up, with fatal results. At the autopsy it was found that there was a thrombosis of both coronary arteries, a rupture of the ventricle, a drawing away of the papillary muscles. It seemed probable that the first anginal symptom was coincident with the thrombosis of the right coronary artery. It was interesting that the pain was on the right side instead of the left, corresponding with the thrombosis of the coronary artery.

DR. CARY said he would like to raise another question, and that was in regard to the true cause of glaucoma. That there was distention of the globe was certain, but that this distention produced blindness was open to question. The cause of the secretion was the real cause of the blindness, and the true cause of the glaucoma. The same thing could be said of angina; that distention of the ventricle gives rise to pain is true, but there were other causes of the anginal symptoms.

DR. J. H. MUSSER said he simply wished to lay stress upon the fact that the dilatation of the heart furnished a safety-valve action for the relief of the pain. Where there was not this dilatation the pain was continuous, and angina pectoris is usually seen in relatively strong and robust men, with strong hearts which do not yield to this intraventricular pressure. There had been no attempt to explain all the causes of angina, because they were not yet all known, but simply to call attention to the relative infrequency of angina in persons with weak or dilated hearts.

DR. J. P. KINNICUTT of New York was of the opinion that thrombosis of the coronary artery was frequently the cause or the paroxysms of anginal pain. The mere stretching of the arterial walls by the embolus was sufficient to account for the pain, for all knew the exquisite pain caused by an embolism in a systemic artery.

PERICARDITIS—SOME POINTS IN ITS DIAGNOSIS AND TREATMENT.

This paper was read by DR. F. C. SHATTUCK of Boston. He pointed out that pericarditis is frequently overlooked because (1) it is not sought for; (2) it might not give rise to symptoms if dry, or if the effusion were small; (3) it is often associated with changes in the lungs and pleuræ which might mask its presence. The shape of the dull area was not, in his experience, pyriform or triangular, but similar to that of general enlargement of the heart. In nearly all his cases he had tapped the pericardium; the point of election for tapping is in the fifth interspace, one or two inches to the left of the left nipple. His best results, in seven operations, had been obtained from this point—forty-six ounces in one case and sixteen in another. He was skeptical of the value of general treatment, and never resorted to any except rest. Alcohol might be useful, but blisters should be avoided. He sometimes used the ice pack when it was grateful to his patients. The answer of Sir William Gull to one of his assistants who sought to apologize for not recognizing a case of pericarditis might be borne in mind by those who were tempted to use energetic remedies in this disease. He replied that it was just as well that he had overlooked it, for if he had discovered it he might have treated it. He realized the serious nature of the operation, but he had never regretted having tapped the pericardium, but he had regretted not having done so. He believed he had saved two lives by the operation, and he thought he might have saved another case by tapping. No hard and fast rules could be laid down for the time of operating or as to the point of election. He had once tapped the pericardium at the costoxiphoid angle in a cadaver, and from his success in this he felt tempted to select the same point in a living patient. In one of his cases the tapping was only temporarily successful, and he had had his surgical colleague open the pericardial sac. This was the only case of this operation at the Massachusetts General Hospital.

DISCUSSION.

DR. JAS. T. WHITTAKER said that the condition is very rarely recognized during life. The symptoms are very obscure, and often unrecognizable. The friction sound is a transitory symptom and hard to demonstrate. He was inclined to give a more important place to tuberculosis as a condition than Dr. Shattuck had assigned to it. At least two-thirds of all cases were due to this cause. The area of dulness can often be more easily mapped out by combined auscultation and percussion. With the patient on his back and a Camman stethoscope in the ears, and lightly resting on the patient's breast, the percussion sounds are much intensified. The operation is not a particularly dangerous one. He had been doing it for many years, and had never seen any bad results. It is even easy, by the simple introduction of the instrument, to feel the pulsations of the heart. In one instance he had attempted to tap the pericardium, and although he got the instrument into the sac, and although he was confident of the existence of effusion, no fluid came through the canula. On withdrawing the instrument he found it plugged with a piece of hyaline cartilage. This taught him the necessity of selecting the point of operation with more care.

Dr. H. A. Hare was of opinion that the danger of wounding the heart is much exaggerated. He had arrived at this conclusion from an involuntary experiment on a young man who was suffering from articular rheumatism. He had intense dyspnea and difficult heart action. Dr. Wilson saw the case in consultation, and a diagnosis of pericarditis was made. He was tapped twice, and although no fluid was withdrawn, the boy was wonderfully improved each time. There was no *post-mortem*, but Dr. Hare was convinced from the subsequent history that the case was not one of pericarditis, but that the young man had a normal heart.

Dr. T. M. Rotch thought this case very well illustrated the danger of tapping the pericardium. There is always a great difficulty in making a diagnosis of pericardial effusion. It is almost impossible to make a diagnosis between dilated heart and pericarditis with effusion, by the usual methods. This is easily seen in the *post-mortem* room. The danger of tapping is increased by the possibility of the heart being bound down in malposition by adhesions. As to the point of election, he had tapped a child with pericardial effusion, on the right side of the sternum. Another point in the physical diagnosis of pericarditis with effusion, which is generally overlooked, is that we will find dulness in the back between the angle of the scapula and the spinal column. He had made this discovery ten years ago, but had never published it.

Dr. Norman Bridge said he was surprised that Dr. Shattuck had made no mention of dysphagia in any of his cases, for he had seen it two or three times.

Dr. James Tyson was especially interested in the matter of the outline of the area of dulness. This area was pyriform, while the shape indicated by Dr. Shattuck was the same as in double enlargement of the heart. For the purpose of mapping out these areas the phonendoscope was of special service. As to the use of blisters in the treatment of pericarditis, he did not think they should be allowed to pass out of use; he did not want to be made to give up his blister. He had always had a great horror of tapping the pericardium until he heard Dr. Shattuck's paper. Then he became bold and thought he might try it, but after hearing what Dr. Hare and Dr. Rotch had said he had retired to his first position.

Dr. A. McPhedran was of the opinion that many of the cases diagnosed as pericarditis were, in reality, cases of myocarditis. This was shown in Dr. Shattuck's cases by the fact that some of his tappings were dry, and he believed that if all his cases had gone to autopsy it would have been shown that they were suffering from myocarditis rather than from pericarditis.

Dr. F. H. Williams thought that the use of the X-ray might clear up the uncertainties between pericarditis and enlarged heart.

Dr. Janeway said that the shape of the dull area in pericarditis with effusion was pyramidal, and he was always able to map out this area. He did not consider tapping a serious operation, and had once accidently punctured the right heart and got blood. No harm resulted from the tapping, and when the patient died, shortly afterward, it was seen that the wound in the heart had healed.

Dr. Shattuck, in closing the discussion, and replying to Dr. McPherdan, said he had had only one case in which there had been no fluid in the pericardial sac. It was true that some of his tappings had been dry, but subsequent tappings in the same cases had been productive.

DIAGNOSTIC AND THERAPEUTIC CONSIDERATIONS WITH RESPECT TO CERTAIN AFFECTIONS OF THE UPPER AIR TRACT,

was the title of a paper read by **Dr. Beverly Robinson** of New York. The paper dealt with the utility of the laryngoscope and rhinoscope, and compared the methods of the German and French schools. Numerous examples were cited to show the contrasts between the general practitioner and the specialist in the treatment of diseases of the upper air passages.

NERVOUS DEAFNESS IN DIPHTHERIA.

A case was reported by **Dr. J. C. Wilson** of Philadelphia of follicular tonsillitis in an adult. There had been moderate fever, occipital headache, *tinnitus aurium et cerebri*. On the fourth day dense follicular exudate was observed on the right tonsil, with conjunctivitis, increasing tinnitus, and deafness. An injection of diphtheria antitoxin serum was given, followed in a few hours by total deafness with slight vertigo, and great chemosis. A gradual defervescence occurred, and was completed by the thirteenth day, at which date there was partial paralysis of accommodation, together with paresis of the extensor muscles of the head, persistent tinnitus, slight vertigo, and absolute persistent loss of hearing. The paper also discussed the rarity of the case, its importance, the bearing of the antitoxin injection to the development of the sequelæ, the general subject of sudden nervous deafness in the infections, and the general question of diagnosis, prognosis, and treatment.

DISCUSSION.

Dr. I. E. Atkinson, in speaking of the uncertain and unsatisfactory regulations which required cultures of all suspected cases of diphtheria to be made by the board of health, related the details of a case in which he had made the clinical diagnosis of diphtheria, while the board of health had made three fruitless attempts to find the Klebs-Lœffler bacillus. He contented himself, however, with the philosophic reflection that the case *was* one of diphtheria, despite the failure of the bacteriologic examination, and he had not pressed the matter upon the officials because he was only too glad to be relieved of the unpleasant necessity of placarding the house. When called to see a

TENDENCIES IN MEDICINE.[1]

BY J. M. DACOSTA, M.D.,
OF PHILADELPHIA.

THE greatest advance of our time— it seems trite to mention it to such an assembly—is the ardent study of the causation of disease. Students have speculated in all ages on the causes of disease; but these have been, for the most part, half-hearted speculations, made so by the feeling of impossibility of reaching a conclusion, or dogmatic assertions that, believed in for a time, soon became of interest only to the curious searchers for fragments on the shelving beach of science. Now, the recognition of minute organisms, their study, their artificial culture and modes of growth, their secretions, their chemical characters, their likes, their antagonisms, have let us into the secrets of another world and are showing us the way in which infective maladies originate and the laws they obey. We are looking for infection in every disease; we are often keenly pursuing it where it probably does not exist; at all events, not in the shape of bacteria, which in our day we accept as a term almost synonymous with infection.

Other than mere bacteriologic work forms a most valuable part of the contribution of the laboratory to the investigation of disease, and in the last decade has placed this investigation on a much higher plane. The microscopic and chemic examinations of the secretions and excretions and of the blood have become our daily duty. The chemic examinations, which, dealing, as they may be made to do, with the constantly varying problems of life in disease, have been temporarily overshadowed by the ardor of bacteriologic research, will, with widening fields, resume their former prominence. The time is indeed at hand in which, without the ready access to a laboratory manned by experts in all these lines, or the association with a trained laboratory assistant, no physician can do his patients, himself, or his science justice.

Closely connected with the laboratory investigation of disease, especially with its chemic investigation, is the study of the effects of the products generated by decomposition of albuminous matter, producing, when developed in the dead body, the substances known as ptomaines, when in the living body, as leucomaines. The recognition of these agents, so frequently poisonous, is explaining many obscure processes, is leading to new and close scrutiny of others and to search after means of neuralizing their toxic influences.

Another of the best results of the achievements of our time is seen in the effacement of the strict division between medicine and surgery, or rather in the recognition that there are no lines separating them, but lines becoming continuous, on which joint action proceeds. We see this in the whole clinical history of appendicitis and its progressive unfolding; the more the medical part is studied and rendered precise, the more exact become the indications for operation and the appreciation of the chances. The same may be said of abscess and of tubercle of the kidney; of the investigations of the character of effusions into pleural, or pericardial, or peritoneal cavity; and of many other well-known conditions that surgeons and physicians are now studying together.

The tendency of our time is to endeavor to overcome disease, and not merely to observe and palliate its ravages. We are going back to the doctrines of our forefathers; abandoned for a time, because, with an expanding knowledge from the study of pathology, the means they possessed were found to be, for the most part, totally inadequate. Thus, there was a period of nihilism and expectancy in therapeutics. But so-called rational expectancy is but a confession of impotency. Now, the tendency is once more aggressive. We are trying directly to choke or to subvert morbid action, and doing this partly through the old, transmitted remedies of former generations, but employed with a better understanding of their real qualities, partly by new agents furnished by chemistry and by constant research in other fields.

One of the most interesting attempts at radical therapeutics is the endeavor to counteract the bacteria of disease by substances that form in the body and which neutralize their toxic products. This antitoxin treatment is brilliant and hopeful, and is being tried in many affections, preeminently in diphtheria, in tetanus, and in erysipelas. It cannot be said that as yet it has led to any great results, though the evidence is decidedly in its favor in diphtheria. It seems scarcely worth while to push it in erysipelas—at least in the erysipelas which the physician sees—for the mortality in this is, under any treatment, very slight. How valuable the antitoxins will prove as preventives remains also to be solved. More productive thus far has been the use of attenuated virus, as, for instance, in Pasteur's treatment of hydrophobia, etc. The effects on tuberculosis must be taken thus far as the expression of hope rather than that of fact. The next decade will prove whether the X-rays, which are making such wonderful additions to diagnosis, will have also their therapeutic triumphs.

---

[1] Abstract of the President's address at the Twelfth Annual Meeting of the Association of American Physicians, Washington, D. C., May 5, 1897.

There are, with all these tendences of our day that work for good, some which, whether growing out of them or whether the exaggeration of old hindrances, have to be, in the interest of true science, strenuously guarded against. One that is very evident is the tendency to immediate generalization. The discovery of every new bacterium is supposed to instantly revolutionize the science of medicine, and is announced with all the air of the unexpectedness of genius.

Fixity of opinion in medicine is a virtue, if the mind remain open to proof and be in sympathy with advance; and it is this freshness of mind, joined to good judgment, which will best estimate the true value of the many facts constantly discovered in an advancing science like ours. Clinical medicine, indeed, must continue to be the final court of appeal for the purposes of the practitioner of medicine. Before that court will come and be listened to with sympathetic interest, as eloquent advocates, those who are presenting the claims of special studies. But these must be well supported and judged in their bearing on the whole before new laws are laid down. And we see that the more we investigate and the more we know the more will old questions assume different aspects, the more they will have to be retested; there is no finality—there can be none—in medicine. When the last word is spoken we shall have a perfect science; until then there must remain for us a certain amount of empiricism, especially in treatment.

It would be, indeed, well if in all our professional literature there were something more of the learning of the scholar and the clearness of the literary artist; men who followed the master, Harvey, in other points besides profound and productive research. A few more Watsons and Pagets, Trousseaus and Hyrtls would make knowledge easier to obtain, more constantly with us, forming much more a part of our daily life and application. It is true that if, in our science, we must choose between profound inquiry and its clear enunciation, we shall choose the former. It is a pity, and it is unnecessary, that there should be any occasion for a choice. The French, with their lucidness in scientific matters, set all other nations an example. The countrymen of Goethe, foremost in investigation, following his avowed contemptuous indifference to style, are the greatest sinners against clearness and vivid expression.

One more tendency of the day let me notice, which is not for good, and undoubtedly retards progress. It is the excessive publication of half-knowledge, of doubtful fact, and of loose inquiry. The propensity for authorship is an old disease, but it has assumed a development commensurate with the prodigious development of everything else in the age in which we live. It is harmless in journalism, less so in literature, but positively dangerous in science; for it fills it with immature or false observation, and takes the time of others to remove the obstructions placed in the stream of knowledge. With some, want of sufficient training leads to it and absence of inquiry into what has been already ascertained; in others, it proceeds from a girl-like genius that, in place of letter-writing, pours itself out in medical periodicals, fascinated by penning sentences full of pseudo-scientific commonplace. It is far from being a disease only of the untried or ignorant; famed workers, too, may succumb to it, listening, perhaps, to the entreaties of friendly and sleepless editors. Who knows that it is not, after all, a physiologic function, giving full play to brain-centers in very rare use—centers situated in what Oliver Wendell Holmes has called the idiotic area of the brain.

But whatever the retarding influences, they are not to any extent checking the onward course of medicine. The numerous inquries, the keen experimentation and close research, the general thoughtfulness, are developing a resistless scientific method; resistless because it is true. Medicine is no longer an art founded only upon empirical observation, no longer a purely deductive science; it is also becoming an inductive one. The great body of the community is touched with friendly interest in watching its growth. With the advance of the scientific method special systems are crumbling; future ones are impossible. There can be no more pathies; the general intelligence will prevent it; for educated men are recognizing the broad base on which medicine is resting, and that truth is sought in it by the same means that are used in physics and in the highest development of other sciences. In our midst with all this, conviction is becoming clearer, purpose waxing more resolute. We see, without pang, castles which have crowned rocks being turned into dismantled memories, because we know that something stronger, that will defy all time, will stand ultimately on the old commanding sites. With everyone of us there is a mission to assist the general advance.

PERITYPHLITIS AND APPENDICITIS IN THEIR RELATIONS TO OBSTETRICS AND GYNECOLOGY.[1]

By PAUL F. MUNDÉ, M.D.,
OF NEW YORK;
PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC AND AT DARTMOUTH COLLEGE; GYNECOLOGIST TO MOUNT SINAI HOSPITAL; CONSULTING GYNECOLOGIST TO ST. ELIZABETH'S AND COLUMBUS HOSPITALS; CONSULTING OBSTETRICIAN TO THE CITY MATERNITY HOSPITAL AND TO THE MOTHERS' AND BABIES' HOSPITAL.

THE recognition of the true pathology of inflammation of the vermiform appendix is an event of comparatively recent date. Formerly, indeed within twenty years, inflammation of the right iliac or cecal region was known as “perityphlitis,” and supposed to be situated in the neighborhood of the typhlon or cecum, the cause of the disease being the transmission of an infection or irritation from the bowel. The connection of the appendix with the inflammation was not suspected. Hence, in former days, the disease was called perityphlitis, and only within the last ten years or so has the term “appendicitis” been adopted. Although a hybrid word, it expresses the condition of inflammation of the vermiform appendix perfectly, and is scarcely likely to be supplanted by the word “scolecitis” (Greek *σκόλεχ*), recently suggested by Dr. Gerster. The word “appendicitis” has, however, one disadvantage when applied to the disease in the female sex, namely, that it conflicts with the name which might be given to inflammation of the uterine appendages, for which the long and cumbersome word, “salpingo-oophoritis” is now used. However, it is not my object to discuss either appendicitis or perityphlitis in a general manner, but to confine myself to these diseases as they may interest the obstetrician and gynecologist.

That such conditions as perityphlitis and perityphlitic abscess exist, entirely independent of the appendix, I know to be the case, and I shall refer to an instance of it in the course of this paper.

Until quite recently, nearly all, if not all, the cases of appendicitis reported in literature occurred in the male sex, as though the disease was limited to that sex. Of course this was not the case, for the female has a vermiform appendix quite as well as the male, and there is no physiologic, anatomic, or pathologic reason why the appendix should not become inflamed quite as readily in the young or adult female as in the male at any age. But certainly the disease was looked upon as occurring chiefly in the male.

The reason for this apparent immunity in women must undoubtedly be sought in the vast preponderance of inflammatory affections of the uterine appendages, pelvic peritoneum, and pelvic cellular tissue, which so overshadowed the intestinal appendix as to cause diseases of this organ to be overlooked and undervalued. I have no doubt that many of us in past years have failed to recognize more than one appendical exudate and abscess, mistaking it for a pelvic cellulitis or peritonitis on the right side; and the error was never discovered, because in those days the abdomen was not so readily opened as now, and even the autopsy failed to explain the true cause of the general peritonitis from which the patient died. A proper consideration of the exact site of the inflammatory product, whether it descended into the pelvic cavity or was situated in or above the iliac fossa, must easily have settled the question. But the idea of appendicitis did not occur to us then as it does now, any more than formerly a tubal pregnancy, particularly after rupture, was recognized as readily as now, simply because we had not then become accustomed to look for that accident, as is now the practice.

I recollect a case seen by me in 1875 in which a hard, painful mass was found in the right ilio-ovarian region, and which I supposed to be an exudate from pelvic peritonitis or cellulitis. Not until two weeks later, when I was asked to see the patient again and found a fluctuating swelling in the median line halfway between the umbilicus and pubes, aspiration of which showed a thin feculent-smelling discharge, did the true nature of the case—a fecal perityphlitic or appendical abscess—reveal itself.

Some twelve years ago I was called to see a girl of fourteen for an obscure pain in the right iliac region which was supposed by the family physician to depend on disease of the right appendages. I detected a resistance at that point and diagnosed a “perityphlitic abscess,” the temperature and pulse indicating the probable presence of pus. On the night before the day fixed for the operation the abscess broke into the bowel, the pus was discharged per rectum, and the tumor and all the symptoms disappeared. I will mention incidentally that I saw a similar occurrence in a boy some twenty years ago, when I was still attending general practice. I failed to make the diagnosis until after the rupture, as the tumor developed in the median line and resembled the distended urinary bladder. But the peculiar odor of the fluid discharged per rectum, the complete subsidence of the swelling and rapid recovery of the boy, made such an impression upon me that I at once recognized the similarity of the two cases when the discharge voided by the girl was shown me. In both of these cases an operation was happily forestalled by the unexpected bursting of the abscess into some portion of the intestinal canal.

---

[1] Read at the Twenty-second Annual Meeting of the American Gynecological Society, Washington, D. C., May 4–6, 1897.

I had almost forgotten these two cases when about five years ago a girl fourteen years of age was brought to my office for a foul-smelling discharge from the vagina which I found to proceed from an opening in the right vaginal wall. The hymeneal ring had been so dilated by the presence of the abscess that a vaginal examination was easy. On probing the abscess it was found to extend up to the crest of the right ilium, where the history stated the pain originally began. Free incision, irrigation, and drainage, resulted in a closure of the abscess. A short time later two instances of appendical abscess, one complicated by abortion, the other by a small ovarian tumor, which completely masked the presence of the abscess (the pain and fever being attributed to a twisted ovarian pedicle), occurred in my service at Mt. Sinai Hospital. Although I was much interested in these cases I did not report them, as I presumed they were not uncommon in general practice, and as I did not then appreciate their close relation to gynecology and obstetrics.

When, however, in September, 1894, a case of appendical abscess during the eighth month of pregnancy, which caused the death of the child and premature delivery through the high temperature (104° F.) produced by the disease, was seen by me in consultation and reported in the *Medical Record* of December 1, 1894, the profession became aroused to the importance of this subject, and reports of similar cases began to appear in the medical journals. One of the earliest articles is by Dr. F. W. Thomason, of Huntsville, Texas (*Medical Record*, September 21, 1895), in which he refers to my case of September, 1894, as "now famous in medical literature." The most complete paper on the subject is by Dr. Robert Abrahams of New York, which he read before the New York County Medical Association on November 16, 1896, and published in the *Americal Journal of Obstetrics* for February, 1897. He limits his remarks to appendicitis complicating pregnancy, and reports seventeen cases observed by him, Wiggin, Gerster, McArthur, S. C. Harrison, Thomason, Crutcher, Hirst, Willy Meyer, and myself.

A very excellent article by H. N. Vineberg on "Acute Catarrhal Salpingitis; its Resemblance to Appendicitis; Differential Diagnosis and Treatment," appeared in the *Medical Record* for November 21, 1896. Of late, reports of cases mentioned in discussions at the various medical societies, in which appendicitis was complicated with inflammatory disease of the right appendages, or in which an inflamed and suppurating tube or ovary simulated an appendical abscess, are increasing.

I myself have had some additional experience, a report of which, with the exception of my most recent cases, will be found in the *Medical Record* for March 23 and October 26, 1895. In these communications I refer chiefly to the occurrence of appendicitis during pregnancy and labor, and call attention to five points in the pathology, diagnosis, and treatment of the disease at these times, namely:

1. The possibility of the occurrence of appendical inflammation, either as a new disease, or as a recurrence of a previous attack at any time during pregnancy, or even during labor and the puerperal state. Indeed, there is no reason whatever why a woman at these times should be more safe from the disease than at any other time.

2. The induction of abortion or premature labor by the acute appendicitis, either in consequence of the local irritation or through the fatal effect on the ovum of the general hyperpyrexia.

3. The difficulty of diagnosis of the true nature of the case, especially when the pain in the right iliac region is masked by the natural labor pains, or the attack occurs after delivery, and the high temperature may be mistaken for that of puerperal septic infection.

4. The necessity for prompt surgical interference, whether the attack occur during labor or the puerperal state.

5. The danger of a greater mortality owing to the possible postponement of the operation in consequence of the difficult diagnosis, or to the risk of genital infection.

In my first reported case I delayed operation until four days after delivery, as the urgent symptoms abated and there appeared to be no immediate danger. Fortunately, the abscess was separated from the general peritoneal cavity by firm adhesions. (The lady has since had a normal delivery at term.) In future I would advise an early operation rather than take the chances of an intraperitoneal rupture of the abscess. I think the danger of a possible septic puerperal infection from the opened appendical abscess far less serious (since infection can be guarded against by careful antisepsis) than that incurred by the always imminent rupture of the abscess and the resulting general peritonitis. In fact, I would treat the case like any other appendicitis, without reference to the existence of pregnancy, labor, or the puerperal state.

I am aware that a number of cases of appendicitis recover without suppuration and without operation. Dr. Thomason's case was such a one. And I must therefore leave the indication for operative interference to the judgment of the medical attendant in the case. But when the pain in the right iliac region is severe, the pulse is rapid and small, and the abdomen tympanitic and tense, no matter whether the temperature is high or not, I believe the safest plan is a speedy incision and evacuation of the pus, if there is any, or, at least, the removal of the appendix. If, in addition to the above symptoms, there be bilious vomiting, and particularly if there be resistance, dulness, or a well-defined swelling in the right iliac fossa, the operation should be at once performed.

If labor is in progress, there should be even less delay than usual in operating when an abscess is suspected, since the uterine contractions may mechanically produce traction on the appendical adhesions and a consequent rupture of the abscess. This seems to have taken place in the case reported by me in the *Medical Record* for October 26, 1895, where there had been a number of previous attacks of pain in the right side several years before, and the acute symptoms of the attack in which I saw her came on a few hours after delivery.

The difficulty of diagnosis of appendical abscess, when masked by septic puerperal symptoms, is illustrated by a case which I saw in consultation about a year ago.

The woman had been delivered four days before of triplets, in the fifth month of gestation. Two weeks previously she had a purulent diarrhea. When I saw her the pulse was 120, the temperature 101.3° F.; there was severe pain in the right hypochondrium, and also tenderness on pressure. The pain and tenderness did not extend down to the crest of the ilium; hence, I excluded appendicitis, but suspected hepatitis or perinephritis. The uterus was prolapsed, the cervix lacerated, and there was a free, offensive discharge. The woman was evidently septic, and I attributed the symptoms to a septic endometritis. At the request of the friends and the physician, the patient was transferred to Mt. Sinai Hospital, where I at once curetted the uterus and packed it with iodoform gauze. Dry cups, followed by hot poultices, were applied to the right hypochondrium. As the condition did not improve, two days later I aspirated in the hepatic and lumbar regions, without securing anything; but on trying again, between the ninth and tenth ribs, very offensive pus was withdrawn. The patient was at once removed to the operating-room, and the ninth rib resected, when an immense abscess was opened, which was evacuated and drained. The patient died two days later, and the autopsy showed that the pus came from the pericecal region, having burrowed its way upward until it became subphrenic. The appendix was inflamed and adherent, but no perforation was detected.

I was reminded by this case of one seen a year before, where a woman whose appendages I had removed for pyosalpinx several years previously, was admitted to my service for severe pain in the right hypochrondium. Seeing that the case was not gynecologic I had her transferred to the general surgical service, where the operation revealed a subphrenic abscess, which had originated in an appendicitis.

The mortality in the cases of appendical abscess, occurring during pregnancy, which have thus far been reported, has been rather high. Abrahams (*loc. cit.*) reports seven deaths out of seventeen cases, or seven deaths out of ten suppurative cases; of the latter all but one were operated upon. This death-rate is entirely too high, and must undoubtedly be attributed to the lateness of the operation, due to the failure to make an early diagnosis, an error for which probably the attending physician was to blame. However, considering the meagerness of our information on this complication of pregnancy up to the last two years, the physician can scarcely be censured for his oversight. Future records will undoubtedly show better results, probably quite as good as those obtained under ordinary conditions in either sex.

So far as the relations of perityphlitis and appendicitis to gynecology are concerned, the cases where the latter affections occur simultaneously with acute inflammation, or abscess of the right uterine appendages, or where one of these diseases simulates the other, are naturally far more frequent than the complication with pregnancy. With the pelvic organs in a healthy condition there is no more difficulty in diagnosing an appendicitis in the female than in the male, with the exception of those cases where the vermiform appendix is unusually long and hangs down into the pelvis. A few cases are recorded where the appendix was found on the left side, being unusually long and having been carried there by intestinal peristalsis. Last winter I removed a perfectly healthy appendix, seven inches in length, which had unexpectedly prolapsed into the vagina through an incision in the posterior vaginal vault made to evacuate the blood from a pelvic hematocele. The appendix evidently must have prolapsed into the pelvic cavity before the hematocele was formed, since the roof of the cavity consisted of fresh adhesions. (The cause of the hematocele, by the way, was a ruptured tubal pregnancy, the sac of which I removed per vaginam; the patient recovered.) With the appendix thus displaced, it is evident that the diagnosis between it, when inflammed, and an inflamed tube might be difficult.

Ordinarily in appendicitis the pain, tenderness and swelling are limited to the spot just above and within the crest of the right ilium, and nothing abnormal can be felt through the vagina. It is only exceptionally that an appendical exudate reaches so low down as to be perceptible through the right vaginal roof; and then it might be difficult or impossible to distinguish it from a perisalpingitis or an adherent pyosalpinx, or even a true pelvic cellulitis, such as is occasionally met with after abortion or delivery at term.

An illustrative case was seen by me in consultation last December. The patient had been ill for six weeks with pain in the right ilio-ovarian region, moderate elevation of pulse and temperature, and coated tongue. The physician, an unusually accurate observer, had examined her per vaginam and made the diagnosis of salpingitis on the strength of an exudate which he felt to the right and in front of the uterus, and treatment had been in accordance. As her condition did not improve, I was asked to see her. Being always suspicious of appendicitis when the symptoms are most prominent on the right side, I made a particularly careful external examination of the right iliac and ovarian regions, and thought I could distinctly make out not only dulness, but also a resistance to pressure in the right iliac region. To be sure, these sensations extended down toward the pelvic region in the median line. Vaginal examination showed the hard, immovable mass in the right anterior fornix previously noticed by the attending physician. Basing on the facts that the dulness and tenderness extended from the vaginal roof up to the right iliac fossa, that the mass felt per vaginam was anterior to the uterus, and not deep in the pelvis (as would have been the case in true pelvic cellulitis or perisalpingo-oophoritis), and that the pulse and temperature (110 and 101.2° F. respectively, continuing for several weeks) showed the probable existence of suppuration, I made the diagnosis of appendical abscess, the pelvic mass being part of the exudate which had not yet broken down. The family physician could not make up his mind to agree to this diagnosis until, the patient having been removed to a private room in Mt. Sinai Hospital, he was compelled to be convinced when an incision in the right semilunar line opened the appendical abscess. The pelvic exudate gradually melted away, and the patient was discharged cured in a little over two weeks. It should be added that the patient had had several attacks similar to this one during the last three years.

In both diseases, appendicitis and perisalpingo-oophoritis, with or without suppuration, the conditions of pain, temperature, pulse, tympanites, fecal evacuations, general depression, reflex vomiting, etc., are very similar, and there is scarcely one special sign which would afford us a decided clue in favor of one disease or the other—except the location of the original pain, which, in appendicitis, is never in the pelvic cavity or in close proximity to the uterus. It is not always in the right iliac fossa, or at McBurney's point, unfortunately, for often the chief pain is felt in the epigastric region, or, at times, even in the left iliac fossa, or the pain is spread over the whole abdomen, and is not, therefore, the valuable diagnostic sign which we wish it were. But bimanual (vagino-abdominal) palpation does not cause pain in appendicitis, unless in the comparatively rare instances where appendicitis and salpingo-oophoritis coexist.

So far as the location of the appendical abscess is concerned, when the original exudate has broken down, it is usually found limited to the normal site of the appendix; but, at times, the pus may burrow upward or downward, making its appearance in the subphrenic region, as in the two cases already related, or point in the median subumbilical line, or burst through the right vaginal, or the anterior rectal wall (one case of each seen by me). In such doubtful cases the true origin of the pus may be suspected only by its characteristic fetid odor and thin, saniopurulent character, which leads the physician to trace the abscess with the probe to the right superior iliac region, and to confirm the diagnosis by a careful recapitulation of the history of the case, which will usually show that the first symptoms of pain and discomfort were experienced in the right iliac fossa.

I saw one such case, about a year ago, late one night, with Dr. Alfred R. Crain, who had been treating the patient for what he naturally supposed to be pelvic peritonitis. She was a virgin, but it was not the hymen which opposed the entrance of my finger into the vagina, but the upper bulging of the posterior vaginal wall. On inserting the finger into the rectum, I came against a tense, fluctuating swelling, which burst almost before I could define its outlines, and a torrent of foul, sanious pus was discharged. Its odor at once revealed to me the nature of the case. I washed out the cavity thoroughly, inserted a large drainage tube per rectum, and, under drainage and irrigation, the temperature fell, and a rapid recovery ensued.

This last winter, a case with the history and symptoms of pelvic abscess was admitted to my service at Mt. Sinai Hospital, and seen by me just as I was leaving the ward.

A superficial abdominal examination showed a well-defined, tense, fluctuating mass on the left side, and without making a vaginal examination (I admit, an inexcusable omission) I put the case down for operation on the next day, my regular operating day, intending to open the abscess by an incision in the left iliac region. When the patient was placed on the table next day, to my surprise, I found the elastic swelling in the median line, and assumed that it was an ovarian cyst and that I had made an error in diagnosis. I, therefore, made a median incision, only to find that the uterus and appendages were normal, and that the swelling was retroperitoneal. I then closed the abdominal incision and made a vaginal examination, which revealed a tense protrusion of the posterior vaginal pouch; on opening this, a large quantity of fetid pus escaped, and a probe passed readily up to the crest of the right ilium. The extension of the swelling to the left side on the previous day was doubtless due to the temporary dissecting up of the peritoneum by the pus.

While the appendical abscess may, and probably more often does, simulate a pyosalpinx, pus-ovary, or pelvic abscess, the reverse may at times occur. That is, a pyosalpinx, or pus-ovary, may become adherent to the peritoneal lining of the right iliac region, and both by rational and subjective signs be mistaken for an appendical abscess. I operated on such a case last autumn, and was immensely surprised on opening the peritoneal cavity in the right semilunar line to find an adherent abscess of the ovary. After removing the pus-sac with the tube, I explored the pelvic cavity through the incision and found an intraligamentous abscess of the left ovary, which I removed through a second (median) incision.

Cases of small ovarian cyst with twisted pedicle on the right side have been reported by Drs. Wm. T. Bull, McBurney, and others, I believe, which were mistaken for appendical abscess.

Recurrent appendicitis may readily be mistaken for inflammation of the right appendages, unless a careful examination is made. Several years ago I saw a young lady in consultation who had had seven attacks of severe pain in the right iliac region during the two preceding years, each confining her to bed for a week. Her physician suspected an oophoritis or salpingitis, and asked me to see her with him. Rigidity of the abdominal muscles necessitated examination under chloroform, when I easily decided that the appendages were normal, and that the appendix was twisted, adherent, and swollen to the size of a lead-pencil.

I confess that I have never been able to palpate the healthy appendix, as Edebohls claims can be done, but I do not doubt that with very thin and relaxed abnominal walls it might be done, just as we can often feel the normal Fallopian tube under like favorable conditions.

Even an experienced examiner may make a mistake in diagnosis in these cases of supposed recurrent appendicitis. Recently a young married woman was sent to me for a constant severe pain in the right iliac region. I found a little below the normal site of the appendix a small, hard, very tender, immovable nodule, which seemed to be intraperitoneal, and which I pronounced to be the swollen and adherent appendix. On cutting down on it through the semilunar line I found that the nodule was a fibrous tumor of the size of a hickory nut and extraperitoneal, but so firmly attached to the peritoneum that a strip of the latter had to be removed with it. The peritoneal cavity having thus been opened, I examined the uterine appendages and, finding the right ovary cystic, resected it.

I have spoken of perityphlitis in the early part of this paper. My experience is based on only one case, that of a lady, fifty-six years of age, to whom I was called in consultation last October.

She had been feeling badly for a week, but had not taken to her bed. Three days before I saw her she was seized with a severe pain in the right supra-iliac region, extending down into the pelvis. A physician was not called until two days later. He found the patient in bed, with a pulse of 120; temperature, 102° F.; abdomen tympanitic, and complaining of great pain in the right side. He suspected pelvic peritonitis, and for that reason suggested a consultation with me. When I saw the case, the temperature was 103°F., the right side of the abdomen, from the iliac fossa up to the twelfth rib, was very tender to the touch, rather hard, and there was decided dulness just above the crest of the ilium, extending rather farther back than is usual in appendicitis. Per vaginam absolutely nothing could be felt. I, therefore, excluded pelvic peritonitis, and made the diagnosis of probable perityphlitis, on account of the location of the pain and dulness. I advised immediate operation; the patient was transferred to a private room at the Mt. Sinai Hospital at once, and I operated four hours after I first saw her. My diagnosis was correct; there was an intraperitoneal abscess behind the cecum, the peritoneal cavity being shut off by adhesions. The appendix was adherent, but normal. It was removed, and the wound packed with iodoform gauze. Recovery was slow but uneventful.

It is evident that the practical point of what has been said about perityphlitis and appendicitis, as compared with salpingo-oophoritis, relates to the differential diagnosis between the two diseases. The diagnosis once made, the treatment, whether medical or surgical, will be conducted on the lines laid down for each affection. I would merely remark that in case of doubt I would prefer making the incision in the right semilunar line, since, if it proves to be an appendicitis (suppurative or not) this is the shortest way to reach the seat of the disease. On the other hand, if the case is found to be one of salpingo-oophoritis, or pyosalpinx, or ovarian abscess, the diseased organ can quite as easily be removed through a lateral as through a median incision.

FETAL TYPHOID FEVER AND THE WIDAL REACTION—REPORT OF A CASE.[1]

BY J. P. CROZER GRIFFITH, M.D.,
OF PHILADELPHIA;
CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA.

THE transmissibility of certain infectious diseases from mother to child has long been an admitted possibility, yet without there being much actual demonstrative proof of the passing of any germ from one to the other. Syphilis can undoubtedly be given by a mother to her offspring, and for years it was just as firmly believed that tuberculosis was constantly transmitted in this way. A certain reaction then took place, and it was claimed that inheritance existed, not of tuberculosis itself, but of a certain susceptibility to contract the disease later. This would appear to represent the true condition in the majority of instances; but there are a number of cases on record in which tubercle bacilli have been discovered in the tissues of fetuses born of women suffering from tuberculosis; and the same has been found equally true of the calves of tuberculous cows.

When we come to a consideration of the acute infectious diseases we find that children may, in rare cases, inherit the disease directly, and be born suffering from it, or may in other rare instances complete the attack while still in utero. This has repeatedly happened in the case of variola, the children being born with the marks upon them. There are several well-authenticated cases on record in which pertussis appears to have been contracted during fetal life; and the fact that infants born of mothers who have had pertussis during pregnancy sometimes exhibit immunity to the disease has been urged as an argument that they had passed through an attack while still in utero. The same reasoning has been applied to rubeola; and it is certain that children have been born with the eruption of measles visible on them. In rare cases newborn children have been found to be suffering from malaria.

With regard to typhoid fever, the question has been more difficult of solution, since the symptoms are less well marked. Yet, cases of apparent typhoid fever in the newborn have been reported by Charceley, and Hastelius found lesions strongly suggesting the disease in a stillborn child of a mother dying from typhoid fever.

It is true that typhoid bacilli have repeatedly been reported as being present in the tissues of fetuses from typhoid mothers; yet, as Dürk has pointed out (*Münch. Med. Wochenschr.*, 842, September 8, 1896), some of these instances must be excluded from consideration, since the investigations were made at a time when the positive recognition of the bacilli was not understood. According to this writer, Eberth (*Fortschr. d. Med.*, B. vii, 161, 1889) was the first to recognize positively the intrauterine infection by the germs. They have also been detected by Hildebrandt (*Fortschr. d. Med.*, B. vii, 889, 1889), Giglio (*Centralbl. f. Gynec.*, No. 46, 819, 1890), Ernst (*Berlin. Klin. Wochenschr.*, 994, 1889), Frascani (*Rivista Gen. Ital. di Clin. Méd.*, 282, 1892), and others.

The detection of the germs being always a difficult matter, the application of the new serum test of Pfeiffer and Widal in the case of the fetus and the newborn is of great interest. As yet but little has been accomplished in this direction. Widal and Sicard (*Bull. de l'Acad. de Méd.*, xxxvi, 347, 1896) obtained the reaction in the blood of the young born of a rabbit which had been inoculated six days before. Chambrelent and Saint Phillippe (*Journ. de Méd. de Bordeaux*, 502, March 15, 1896) found it in the blood of a typhoid mother, and also in that of the child born at the eighth month of pregnancy. The child evidently was ill, and exhibited an enlarged liver and a bronchial catarrh, but its symptoms were indefinite, so far as any indication of typhoid fever was concerned. No statement is made with regard to the child's temperature. Etienne (quoted by Widal and Sicard, *loc. cit.*), on the other hand, failed to find the reaction in the blood of a fetus, although that of the mother responded positively. Charrier and Apert (*La Méd. Mod.*, No. 11, 1896) also failed to find a reaction in the blood of a three-months' fetus, although the blood from the placenta gave it.

In this connection the following instance is of interest: A family epidemic of typhoid fever occurred in the practice of Dr. J. M. O'Malley of Philadelphia, and the father, mother, and three children, the oldest being five years of age, were brought to St. Agnes Hospital during my term of service there. On November 18, 1896, the mother, still ill with fever in the hospital, gave birth, at term, to a well-developed child. It is uncertain just how long she had been ill at this date, for the attack was a rather light one; but rose spots were present on admission on November 13th, and by November 23d the temperature had fallen to normal. It is safe to conclude that the attack was probably in the third week when labor took place. The infant seemed healthy in every respect, except for a slight transitory jaundice. The temperature taken for a couple of days was normal; and as the infant remained entirely well, to all appearance, no further records were made. Blood was taken from the mother and from the child, but, through an error, the examination was of no value. Early in January, the child being then about seven weeks old, a second specimen of blood was obtained, and submitted to Dr. Peckham, at the Laboratory of Hygiene of the University of Pennsylvania. Widal's test showed that in four minutes the bacilli became much less active, and began to collect in groups, and that some little time later they became agglutinated.

---

[1] Read before the Philadelphia Pediatric Society.

The conclusion that must be drawn from this case is either that the child had had typhoid fever in utero, and recovered after a very short attack, or that the agglutinating principle had passed through the placenta from the mother to the fetus, without the latter having contracted the disease at all. How the case should be interpreted it is impossible to determine, in the present state of our knowledge. There remains also the hypothesis that the child had imbibed the principle with the mother's milk, but this seems unlikely. Analogy to other infectious diseases, and the fact that fetal typhoid fever does occur, as already pointed out, render the first supposition most probable, *viz.*, that the child, when born, had already had an attack of the fever.

SEPTIC PERITONITIS CONSIDERED FROM THE CLINICAL STANDPOINT.[1]

BY GEORGE RYERSON FOWLER, M.D.,
OF BROOKLYN, N. Y.;
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC; SURGEON TO THE METHODIST EPISCOPAL HOSPITAL, AND TO THE BROOKLYN HOSPITAL.

Classification.—For the purposes of the practical surgeon a good working classification of septic peritonitis is a desideratum at the present time. Without detracting in the least from Professor Senn's admirable groupings under the headings of anatomic, etiologic, pathologic, bacteriologic, and clinical, it must be confessed that in all probability the last-named, with perhaps some modifications, will be found most acceptable to the every day practitioner.

Custom has sanctioned, to a certain extent, the use of the term "general septic peritonitis." The term "diffuse peritonitis," however, is more generally and logically applicable than that of "acute general peritonitis," for the reason so cogently stated by Dr. Abbe that it is impossible in any given case to state that absolutely every portion of the peritoneum has been invaded. For this reason, therefore, the term "diffuse septic peritonitis," it would seem, is to be preferred to that of "general peritonitis."

So too, with the term "perforative peritonitis." This carries with it the etiologic factor involved in its occurrence, and conveys at once the idea of the possibility of successful remedial measures and the necessity for their immediate application, if the patient is to obtain the best results from surgical intervention.

"Circumscribed" or localized peritonitis is likewise a term which appeals to the surgical clinician. Every practitioner realizes what is to be confidently expected under conditions of strict localization of peritoneal inflammation, provided proper and timely surgical measures are introduced into the case. If a relatively positive diagnosis of localization of the peritoneal inflammation, as distinguished from the diffuse form, can be made, a weight of anxiety and responsibility is lifted from the shoulders of the attendant.

The more recently introduced term "hematogenous peritonitis" likewise has its uses, although the rarity of the condition is now generally recognized. It is certainly to be preferred to the sometime popular, although awkwardly expressed, "cryptogenic septopyemia, a term which savors, to a great extent, of an attempt to take refuge behind the barrier of a high-sounding name in order to escape the necessity of exposing our ignorance.

The frequent occurrence of septic peritonitis of puerperal origin is a sufficient warrant for the use of the term "puerperal peritonitis," aside from the fact that the condition presents striking clinical peculiarities, as well as definite therapeutic indications. The obstetric surgeon particularly, will, without doubt, endorse the retention of this term in the nomenclature of disease.

Although no sharp line can be drawn between the peritoneum of the pelvis and that of the cavity of the abdomen, yet the clinical picture suggested by the term "pelvic peritonitis," if it be understood that by this is meant a peritonitis originating from the female genitals, appeals at once to the experienced practitioner. While pelvic peritonitis is circumscribed peritonitis in a sense, yet the conditions present, as well as the etiologic factors introduced, differ so widely from localized peritonitis as generally understood, that there would appear to be no good reason for dropping this term from general use.

The form of local peritonitis embraced under the general head of "subphrenic abscess," has only recently been removed from the class of cases which permitted of diagnosis in the dead-house almost exclusively. The condition now claims attention at the hands of the clinical investigator, and instances are multiplying daily which serve to demonstrate that a proper appreciation of the conditions present is not only possible at the hands of skilled consultants, but that its recognition by the average medical attendant is demanded as well. Inasmuch as these abscesses have for their manifestation a localized suppurative inflammatory lesion of the peritoneum, either alone or in connection with an infection of the connective-tissue proliferation involved in the formation of peritoneal adhesions, the substitution of the term "subdiaphragmatic peritonitis" for "subphrenic abscess,'' appeals at once to our reason and commendation.

---

[1] A contribution to the discussion upon "Peritonitis" at the Fourth Triennial Congress of American Physicians and Surgeons, Washington, D. C., May 4–6, 1897.

Prognosis of Bacterial Invasion of the Peritoneum.—Inasmuch as the general consensus of opinion at the present day among investigators holds the practitioner to the view that peritonitis is exclusively of bacterial origin, the question of prognosis of infectious peritonitis, in the general sense, as in inflammatory infectious conditions elsewhere, simply relates to the balance to be struck between virulency and extent of infection on the one hand, and the degree of vital resistance on the other. With a small amount of even a comparatively innocuous germ present, a fatal peritonitis may follow prolonged handling and consequent extensive abrasions of the peritoneal surfaces, and a comparatively slight traumatism, in the presence of a streptococcus pyogenes infection, may be followed likewise by a fatal result. Further, it has been shown by Grawitz that the peritoneum is tolerant of a certain amount of even highly infectious material, provided there is nothing present that can furnish the pabulum necessary for the growth and increase of the bacteria. Up to a certain point the serous membrane is capable of destroying the bacteria, but beyond this its power ceases, and the irritating properties of the toxic products of the microorganisms assert themselves. Finally, it should be borne in mind that it is not necessary for bacteria to multiply in order to produce peritonitis. Their contact with the peritoneum under circumstances which likewise become the occasion for transudation of serum, effusion of blood, or injury to and perhaps sloughing of tissues, or the simultaneous entrance of other substances which may serve as proper nutritive material, such as feces, affords opportunity for the production of those toxic substances upon which their irritating properties depend, without the necessity for increase in number of the bacteria themselves.

The methods of invasion of the peritoneum will largely govern the outcome of the infection. These methods of invasion are self evident. They include introduction from without through wounds involving both skin and peritoneum; passage through perforation, the result of a traumatism or destructive inflammatory lesion of some hollow viscera; by penetration of the walls of the viscera because of the impairment of the nutrition of such wall; by progressive and continuous growth of bacteria in the substance of the wall of a viscus the seat of a septic inflammation, such as the uterus; and finally, by infection through the blood- or lymph-vessels from some more or less distant focus.

The occurrence of peritonitis without the actual presence of bacteria is of great interest in this connection. This may occur if their toxins reach the serosa, which they may do, by penetration of the visceral walls without the presence of any actual lesion. It is now likewise believed that the bacteria themselves may pass through a visceral wall without multiplication, as well as without exciting any apparent disturbances in those tissues, as in the instance of the wall of a hernial sac.

A further question of great interest in connection with this subject is that of the germicidal power of the serous effusion of the peritoneal cavity. Like the blood serum elsewhere, the serum of the peritoneum possesses to a certain extent the power of destroying even the most virulent microorganisms. There is a limit to this power, however, and when this is reached the bacteria remaining undestroyed find at once the proper pabulum for their numerical increase, as well as the development of the toxic substances upon which their pathologic properties depend. To this germicidal power of the peritoneal effusion upon the one hand, and the now well-known fact first established by the experiments of Wieland that the bacteria in encapsulated abscesses in the peritoneal cavity tend to die out upon the other, is to be attributed the occasional recoveries ensuing in instances where the operative procedure reveals a large amount of thin and opaque serum, the result of rupture of a seropurulent intraperitoneal collection, with an appendical lesion as the original focus of infection. The intestines float in an abundance of this fluid, yet both the visceral and the parietal peritoneum are scarcely injected, much less actively inflamed. A number of such instances have come under my observation in which uninterrupted recovery has followed incision, removal of the original focus of infection, and gauze drainage. In none of these cases have I been able to directly demonstrate bacteriologically the sterility of the abdominal fluid, but this does not alter the fact that the recoveries were due either to the germ resisting and destroying powers of the peritoneum, to a slow process of sterilization of the contents of the original encapsulation, or both. Besides, no amount of negative evidence in a test-tube appeals so strongly to the surgeon's senses as the presence of normal intestines floating about in sero-pus, the latter bathing everything in sight—and yet not the slightest trace of infection, as evidenced by tinge of abnormal hue, to be seen, to say nothing of the circumstance of recovery without the supervention of the first symtom of local or constitutional disturbance.

The most dangerous of these modes of entrance is that which involves a perforation of the intestinal wall of the small intestine, and the least dangerous that which occurs in connection with a wound of the abdominal wall. In the first mentioned, not only is there a great number of bacteria which escape into the peritoneal cavity, but these are most virulent in character and are accompanied by toxins, the result of their growth in the intestinal canal. There likewise is deposited upon the peritoneal surfaces fecal matter which acts in the dual capacity of a pabulum for the growth of the bacteria, and an irritant which excites serous exudation. The latter, as soon as its germicidal power is exhausted; also becomes a rich culture medium for the propagation of the germs. It is this "concatenation of adverse circumstances" which accounts for the high mortality following this accident. The size of the perforation and the rapidity with which the contents of the intestine escape will govern, to some extent, the prognosis in cases of intestinal perforation. When the small intestine is the seat of the perforation the fecal matter may be poured out rapidly and a diffuse septic peritonitis from mixed infection promptly follow. In perforation involving the large intestine the exit of fecal matter may be comparatively slow; adhesive protective barriers are thrown out before diffusion of the infecting agents occurs. The infection is thereby limited and a localized suppurative peritonitis follows, as, for instance, in peri- and paracecal abscess (suppurative perityphilitis).

If, however, a diffuse instead of a circumscribed suppurative inflammation follows the infection, as occurs in the great majority of perforations involving the small intestine, there occurs a train of most dangerous symptoms due to the absorption of septic material from the extensive surface area of this enormous lymph sac.

The least dangerous of the modes of entrance is that which occurs in connection with a wound of the abdominal wall. But a comparatively small number of bacteria are introduced in this manner, probably not more, in the majority of instances, than the peritoneum itself is able to destroy by its serum. These circumstances explain the comparative immunity from danger of many cases of abdominal section for non-suppurative lesions of the uterine appendages at the hands of surgeons who boast of their neglect to protect their patients by the employment of an antibacterial operative technic.

Concomitant circumstances may arise to render the last-mentioned mode of bacterial invasion most dangerous, as, for instance, the simultaneous occurrence of contusion of the peritoneal surfaces, laceration of some of the hollow viscera, the occurrence of hemorrhage, or the presence of a foreign body. Per contra it may happen, as before stated, that a small perforation with slow escape of the contents of the intestine may lead to encapsulation by adhesive barriers and protection of the general peritoneal cavity.

Between these two extremes are to be mentioned, in the order of their gravity—first, invasion through perforations or wounds of viscera, other than intestine, including the kidneys, pancreas, and biliary ducts, ureters, etc., and the eruption of a neighboring abscess, save only when the pus of the latter is sterile. Second, the entrance of bacteria by continuous inflammatory growth through the walls of a portion of the intestinal canal or other hollow viscus. While the mode of invasion here is dangerous from the fact that a large number of bacteria may find their way to the peritoneal surface in a short time, the method of entrance may be resisted by the formation of adhesions upon the menaced serous surface. As an instance of this manner of bacterial invasion may be mentioned the successive occurrence of endo-appendicitis, parietal appendicitis, and finally peri-appendicitis. Third, infection of the peritoneum by way of the Fallopian tubes. The comparatively lessened dangers of this route of infection relate (*a*) to the fact that the source of bacterial supply is not large, the endometrium possessing a high degree of vital resistance and its secretion rendering its cavity in most instances sterile, as shown by Warbasse's investigations; (*b*) to the relatively low grade of virulency of the two kinds of bacteria most frequently found in tubal infection, namely, the gonococcus and the bacillus tuberculosis; and (*c*) ample opportunity is usually afforded for the production of competent adhesive barriers, including those which seal the opening of the tube and confine the infection to the latter and its immediate vicinity. Fourth, those cases in which the bacterial migration takes place through the wall of the intestine as the result of nutritive disturbances of the latter, such for instance as occurs in strangulated hernia. Comparatively few bacteria escape in this manner, while at the same time there is a copious effusion of serum. The germicidal power of the latter is sufficient to destroy the bacteria if the latter are not too numerous. This accounts for the fact that in later years other sources of infection being guarded against, relatively few cases of diffuse peritonitis follow operations for strangulated hernia, unless gangrene and perforation of the bowel wall has taken place.

In estimating the prognosis of peritonitis the practical surgeon will be compelled to take into account the source and virulency of the infection, the mode of entrance of the bacteria, the concomitant circumstances of injury to the viscera, hemorrhage and large serous exudations, and last but not least, the extent of the localization of the infection on the one hand and its generalization on the other. A case of the most violently infectious peritonitis, if localized, may recover, providing proper and timely surgical aid be rendered, and its suppurative products evacuated. It is equally true, likewise, that a comparatively mild, yet widely diffused infection may destroy life, the general system finally becoming overpowered by the toxic products furnished by absorption from an extensively involved area of serous membrane.

Treatment.—With the measures designed to meet the conditions present in a localized suppurative peritonitis, I need scarcely detain you in this discussion. Free incision and proper drainage cover the ground completely. The large majority of cases so treated recover as promptly and satisfactorily as where the same principles of treatment are applied to a suppurative collection elsewhere. In the very recent past the almost unqualifiedly favorable prognosis which the surgeon was able to give in cases of localized suppurative peritonitis was as absolutely reversed in the case of advanced diffuse septic peritonitis as is the day removed from the night, no matter what treatment was pursued. So great are the difficulties in the way of the complete emptying, disinfecting, and draining of the peritoneal cavity, and so dire are the effects upon the vital centers of the enormous quantities of toxic products which find their way from the extensive area involved in the infection, that the surgeon has been almost absolutely without resource in the face of this condition of affairs. He is handicapped at every turn. Persistent vomiting and the early intolerance of the rectum to nutrient enemata prevent him from reinforcing the patient's fast-waning strength, and paralysis of peristalsis robs him of the most efficient non operative method of drainage of the peritoneum. The passage of fecal matter into the stomach adds the damaging effects of stercoremia to the already existing toxemia. These, together with the weak and rapid pulse, vasomotor paralysis, and mental hebitude, combine to stamp the condition as almost absolutely hopeless.

Before these symptoms of systemic infection have advanced to this stage, however, there is a period varying from a few hours to a day or two, during which these symptoms are less aggravated or perhaps absent, and yet sufficient evidence of peritoneal inflammation is present to base a diagnosis upon. Herein resides the surgeon's opportunity. In proportion to the ability on the part of the medical attendant to recognize the true state of affairs early, and his willingness to share the responsibility of the case with the surgeon on the one hand, and the skill, judgment, and particularly moral courage of the latter on the other, will the prognosis in peritonitis improve.

During the past two years there have been a number of cases of diffuse septic peritonitis operated upon successfully, and the matter has reached a stage where the surgeon's margin in escaping responsibility in not operating is becoming narrower and narrower. While there may be cases here and there where the patient's doom is sealed from the very commencement, yet, in view of the knowledge derived from the bacteriologic laboratory and experimentation upon animals, it is difficult to conceive of such a case. If the Lembert suture could close the perforation immediately upon its being made, or the gauze drain carry off the septic products as soon as these are produced, what, other things being equal, would kill the patient?

Still another ray of light has been cast into this dark recess of the surgeon's domain. Encouraged by the success that has followed the antitoxin serum treatment of diphtheria, experimenters have sought to produce an antitoxin to other pathogenic bacteria. The fact that the streptococci are of such importance as etiologic factors in phlegmonous inflammation, and are found so frequently associated with other micro-organisms in the most severe and complicated forms of infectious disease have led to a careful study of this microbic agent. As a result of these studies much has been learned from a biologic standpoint; what is of greater importance, however, if the hope of the present is realized in the future, an antitoxin has been developed for this germ.

Although not all experiences with the treatment of septic peritonitis by means of the streptoccus antitoxin have been favorable so far as a successful result is concerned, yet they have been such as to warrant further investigation of the new agent as a means of combating the general infection.

It would be out of place in a discussion of this character to enter elaborately into the subject of serumtherapy, but I may be pardoned if my estimate of the importance of this subject leads me to refer to the recent experiences of some of my colleagues in New York, as well as of my own. The interest in these cases is enhanced by the fact that some of them have not yet been published.

Dr. Howard Lilienthal has kindly placed at my disposal abstracts of three cases bearing upon this question. The first was a case of perforative appendicitis followed by diffuse septic peritonitis. At the operation (June, 1896) pus and feces were present in the peritoneal cavity. One injection of 12½ c.c. of the streptococcus antitoxin was administered. A secondary intraperitoneal abscess required surgical intervention some days later. Recovery ensued. The second was a case of diffuse peritonitis from disease of the uterine appendages treated by operation. The temperature dropped to normal after one injection of streptococcus antitoxin. Death followed from paralysis of peristalsis. The third case was that of a boy of ten who was suffering from diffuse peritonitis caused by appendicitis, and who was almost moribund at the time of the operation. The patient died even though the antitoxin was administered.

Dr. M. R. Richard, of New York, in a personal communication gives me the details of a most interesting experience with the serum of Dr. Marmorek of the Pasteur Institute in Paris. The patient was also seen by Drs. Mundé and Brettauer. The case was one of post-puerperal infection. Thorough curettement under chloroform failed to effect any amelioration in the symptoms. Five days afterward the temperature was 106.2° F., the pulse 150, and the respirations 46. There was a fall of 2° one hour after a 10 c.c. injection of the Marmorek serum, and a further fall of 2.2° after the second, making a total fall of 3.8° in twelve hours. A fall of 6° took place in thirty-one hours. This patient recovered.

My own case is as follows:

A. V., aged twenty-nine, was seen by me in consultation late in the evening of April 9, 1897. A history of at least three previous attacks of appendicitis, occurring within the last four years, was obtained. Twenty-eight hours prior to my visit the first symptom of the present attack of appendicitis began. These progressed rapidly, and perforation had evidently taken place within twelve hours of the commencement of the attack. Efforts to obtain catharsis by means of calomel and sulphate of magnesia had proved ineffectual. When seen by me the temperature was 103.5° F., and the pulse 130. The abdomen was distended, everywhere tympanitic, and extremely rigid. Maximum point of tenderness just below the umbilicus.

He was removed to the Brooklyn Hospital and the abdomen opened in the median line. A diffuse septic peritonitis with pus and fecal matter in the cavity of the peritoneum was found. About fifteen inches of ileum, was bluish black in color and necrotic in spots, and was bound firmly by adhesions in a mass in the median line. Parting the adhesions, a gangrenous and perforated appendix was discovered and removed. The cavity of the abdomen was thoroughly irrigated with sterilized salt solution, the incision being extended to gain access to the regions of the spleen and liver. The cavity was drained by gauze in four directions, supplemental incisions being made for the purpose, *i.e.*, in the hepatic, splenic, and iliac fossæ; gauze drains were also led out of the upper and lower angles of the median wound. Copious absorbent dressings were applied.

Within six hours of the operation the temperature dropped to 98.6° F., the pulse to 110. At the end of twelve hours the temperature was found to be rising, having reached 100° F. and the pulse 140. At this time 12.5 c.c. of streptococcus antitoxin was injected in the left buttock. In spite of this, however, the temperature rose in eight hours to 101.2° F. A second injection of 12.5 c.c. was now given. In the course of the following eight hours the temperature had fallen a trifle over 1 degree, and the pulse to 116. A third injection was followed by another fall of .6 degrees, the pulse-rate being 94. In the course of the next eight hours the temperature rose a degree, and the pulse to 116. A fourth injection of 8.3 c.c. was now administered. No change in pulse and temperature followed this injection. A fifth injection of 8.3 c.c. was given after six hours; this was followed by a fall of the temperature to normal, but the pulse rose to 120. An injection of 8.3 c.c. every six hours was followed by a practically normal temperature, the pulse ranging from 114 to 120 for the next twelve hours. The temperature then rose to 101° F., and the pulse to 126. From this time until his death, which took place on the fifth day following the operation, and the sixth of the disease, the temperature was practically uninfluenced by the serum, although the pulse-rate remained in the neighborhood of 100; just before his death, counted at the heart, it was 80.

Fecal vomiting, due to paralysis of peristalsis, was present at intervals for forty-eight hours before death. This was met with frequent lavage, the stomach tube being utilized after each lavage for the introduction of liquid food. The usual heart stimulants were likewise employed throughout the case. The *morale* of the patient was excellent until a few hours before death. There was likewise a complete absence of vasomotor paralysis until an hour before the lethal result. The daily excretion of urine was uninfluenced, and the slight albuminuria present before the operation was neither increased nor diminished by the treatment; 250 c.c. of the serum in all was used.

The autopsy revealed a gangrenous condition of the parietal and visceral layers of the peritoneum throughout almost the entire region of the small intestine. The peritoneal cavity everywhere was dry and clean. The most indubitable evidences of a diffuse, unlimited peritonitis were present.

The fact that the drainage was so complete, as revealed by the autopsy, taken in conjunction with the somewhat contradictory results of some of the injections as compared with others, leads me to express some doubt as to the influence which the serum exercised upon the course of the case.

The case reported by Dr. Egbert H. Grandin[1] is worthy of comment. The case was one of suppurative peritonitis due to a gangrenous and perforated appendix, which was removed by operation. The patient pulse was 90 and temperature 100° F. Hot salt water irrigation and gauze drainage from the median wound were practised. After a few days a pus cavity containing over a pint was evacuated on the left side, just above Poupart's ligament, a counter opening being made at the same time into the vagina, thus establishing thorough drainage. Upon the following day another series of pus pockets was opened, irrigated, and drained. Upon the next succeeding day another incision uniting the two last was made upon the left side of the abdomen. It was upon this day that the streptococcus antitoxin was first used.

---

[1] *Medical Record*, New York, 1897.

This patient recovered. In view of the fact that the reporter, in the early part of his article, expresses a doubt as to whether the entire abdomen had been infected, and later on relates how he opened and drained circumscribed collections of sero-pus; and the further fact that these most valuable and ordinarily efficient measures in circumscribed peritonitis had been instituted before the administration of the serum, there must remain a very decided doubt as to the part which the antitoxin played in bringing about the favorable result.

In perforative peritonitis, as before stated, a mixed infection is present in the vast majority of cases; while it is probably true that the streptococcus pyogenes is among the most virulent, if indeed it is not the most virulent microbic organism present under these circumstances, it is not by any means the only one capable of destroying life. With this fact before us, and the knowledge that the antitoxin of one class is powerless against another, it at once becomes evident that, in order to proceed rationally, the surgeon and bacteriologist must work side by side, an antitoxin to each pathologic bacterium being furnished, according to the findings.

And this is as it should be. The bacteriologist for years has been working out biologic problems in his laboratory, but only here and there has the every-day practitioner been able to avail himself of the knowledge thus gained. Among the notable instances of the practical application of this knowledge is the treatment of diphtheria by means of the antitoxin of its own infecting agent. If the claims made for this method of treatment are well-founded, there is no reason why immunization against the toxic substances produced in the life history of other germs should not be secured, providing the law that each microbic organism is capable of producing an agent antagonistic to its own toxic products—in other words, an antitoxin—holds good in all cases of bacterial infection. Now let bacteriologic science step forth and take its place among the specialties in practical medicine, for such a place surely awaits it. Backed by a diagnosis based upon a properly conducted bacteriologic examination, reinforced by means of systemic infection, if this occurs, and stimulated by a reasonable hope of eventually saving the patient's life, the surgeon will be emboldened to enter upon those extensive operations which, up to this time, while perfectly understood and appreciated by the bulk of the profession, have served not only to cast undeserved opprobrium upon the individual operator at the hands of the laity, but to bring into disrepute surgical science and art as well.

THE AMERICAN PEDIATRIC SOCIETY'S REPORT ON THE COLLECTIVE INVESTIGATION OF THE ANTITOXIN TREATMENT OF LARYNGEAL DIPHTHERIA IN PRIVATE PRACTICE. 1896–1897.

IN this second and supplementary investigation, the aim has been to ascertain: (1) What percentage of cases of laryngeal diphtheria recover without operation under antitoxin treatment? (2) What percentage of operated cases recover? The report now submitted may properly be limited to answering these two inquiries.

Since the beginning of the general use of intubation, no disease has been more thoroughly observed and more fully reported than laryngeal diphtheria. Operative cases, especially, without hesitation, whether ending fatally or favorably, have been fully and promptly put on record. The result has been a collection and tabulation of cases available for control, such as few diseases offer. There are thousands of intubation cases before the days of antitoxin, and thousands since, available for comparison. It is then to cases of laryngeal diphtheria, especially those requiring operative interference, that we may apply the crucial test of the value of the antitoxin treatment.

Sixty thousand circulars containing the following questions have been distributed:

Age of patient?

Diagnosis confirmed by:

1. Presence of other cases in the family?
2. Appearance of membrane elsewhere?
3. Bacteriologic cultures?

How many days and parts of a day after the first appearance of the disease was antitoxin first administered?

How many doses of antitoxin were administered?

Dose of each injection in antitoxin units?

Whose antitoxin used?

Non-operative cases—evidence of disease:

Hoarseness?

Aphonia?

Stenosis?

Operative cases:

1. Intubation? On what day?
2. Tracheotomy? On what day?

How long, in days and fraction of a day, was tube in the larynx or trachea?

Sequelæ (in recoveries):

1. Bronchopneumonia?

2. Paralysis?
3. Nephritis?

Death, cause of, and on what day?

1. Bronchopneumonia?
2. Extension of membrane to the bronchi?
3. Sudden heart paralysis?
4. Nephritis?
5. Sepsis?
6. Accidents of operation?

Recovery?

Remarks, especially on fatal cases?

These circulars were distributed throughout the United States and Canada, the following means being employed: Contributors to first reports, members of the Society acting as agents for their respective localities, boards of health, local medical societies, and antitoxin manufacturers. At the outset, in this connection, it is a pleasure to acknowled that the labors of the committee have been much lightened by the uniform good-will of all addressed, more aid coming spontaneously than in the previous investigation. It is also a pleasure to especially acknowledge the Society's indebtedness for efficient aid in distributing circulars and securing returns to the H. K. Mulford Co., Parke, Davis & Co., Lehn & Fink (Gibier's), the Health Departments of Chicago, St. Louis, New Orleans, Denver, San Francisco, Boston, Washington, Buffalo, Providence, Ann Arbor, Newark, Montreal, Toronto, and others.

To the New York Health Department is due the thanks of the Society for every possible courtesy in distributing blanks, and, through their inspectors, of securing returns of operative cases.

In order to reduce sources of error it was desirable to bring together a large number of cases, from widely distributed localities, from many different observers and operators, and from a period of time including all seasons of the year. All returns have been examined by the committee, and only such cases accepted as bore satisfactory evidence that they were first of all diphtheria, and secondly that the lesion had invaded the larynx.

A total of 1704 cases of laryngeal diphtheria are ours for present study. A few cases (228) had not satisfactory evidence that there was laryngeal involvement; indeed, some were reported through misunderstanding the fact that only laryngeal cases were wanted, and a few were reported in which there was no mention that antitoxin was used. These cases are, of course, not included in the number referred to above; 218 of them ended in recovery and only 10 were fatal.

In a total of 1704 antitoxin-treated cases of laryngeal diphtheria, there was a mortality of 21.12 per cent. (360 deaths).

TABLE OF ALL CASES SHOWING AGE AND RESULT OF TREATMENT.

	Fatal Cases.	Recoveries.	Totals.	Mortality.
1 year and under,	25	35	60	41.66 per cent.
1 to 2 years,	77	219	296	26.01 per cent.
2 to 3 years,	81	260	341	23.75 per cent.
3 to 4 years,	42	216	258	16.27 per cent.
4 to 5 years,	47	160	207	22.70 per cent.
5 to 10 years,	72	345	417	17.26 per cent.
10 to 15 years,	9	64	73	12.32 per cent.
15 to 20 years,	2	24	26	7.65 per cent.
Over 20 years,	5	17	22	22.72 per cent.
Unknown,	0	4	4	
	360	1344	1704	21.12 per cent.

CASES NOT OPERATED ON.

The first inquiry of the circular was What percentage of cases of laryngeal diphtheria recover without operation under antitoxin treatment?

Of 1704 total cases, 1036 were not operated upon (60.79 per cent). Of these, most did not require operative interference, a few cases were thought to require it, but operation was refused. All cases are included, and it will be noted there are no eliminations.

Among the 1036 cases not operated on, there was a mortality of 17.18 per cent. (178 deaths), or, to answer the inquiry of the circular exactly, of 1036 cases not operated on, 82.82 per cent. recovered (or 858 cases).

As good as is this percentage of recovery in so large a number of cases of diphtheria of the severest type, it is believed it is not as good as it ought to be. Cases of laryngeal diphtheria not requiring operation, according to the testimony of consulting intubationists, are seldom heard from a second time, and less often find their way into reports. It was formerly estimated that about 10 per cent. of cases of laryngeal diphtheria recovered without operation. The present report shows that in 1036 cases 82.82 per cent. recovered.

CASES OPERATED UPON.

In analyzing this class of cases, it is believed a more exact conclusion as to the value of the antitoxin treatment can be arrived at than in the non-operative.

There will be entire harmony of opinion as to the severity of laryngeal diphtheria which requires operative interference. In the early days of intubation it was customary to speak of the percentage of recoveries, and twenty-five per cent. and twenty-seven per cent. were considered good results. In the last report the recoveries had crept up so high in the one hundred cases that it seemed more natural to speak of the percentage of mortality.

In this connection it is interesting to inquire what were the most reliable statistics of intubation, taking cases as they occurred, without selection, in pre-antitoxin days. In 5546 intubation cases collected by McNaughton and Maddren in 1892, the mortality was 69.5 per cent., or, to bring the facts into line, 30.5 per cent. recovered.

O'Dwyer's personal experience, in private consultation, brings us more nearly face to face with the old-time experience with diphtheria. Note that the following 500 cases came under the observation and care of one practitioner, a skilled operator, extended over a dozen years of time, and therefore included all types of the disease.

Exclusive of the first 100 cases of intubation, which he (O'Dwyer) regards as experimental, the results stand as follows:

2d, . .	100 intubations,	recoveries,	27 per cent.
3d, . .	100 "	"	30 "
4th, . .	100 "	"	26 "
5th, 70 in the	100 "	"	27 "

Total percentage of *recoveries*, 27.56 per cent. When he had reached 70 in the fifth hundred something occurred which carried the phraseology up over the divide, so that it was appropriate to speak of percentage of *mortalities*. At this point in history antitoxin arrived, and interrupted forever the old series. In O'Dwyer's next fifty-nine cases the *mortality* was fourteen deaths, or 23.7 per cent.

In a total of 1704 laryngeal cases there were 668 cases operated upon. In the 668 there were 182 deaths, or a mortality of 27.24 per cent. In the former report, in 553 intubated cases the mortality was 25.9 per cent. In approximate figures there is a difference between 27¼ per cent. and 26 per cent.

SUMMARY.

Sixty thousand circulars were distributed throughout the United States and Canada.

Time allowance, the eleven months ending April 1, 1897.

Whole number of cases in this report, 1704; mortality, 21.12 per cent. (360 deaths).

The cases occurred in the practice of 422 physicians in the United States and Canada.

Operations employed:

(*a*) Intubation in 637 cases; mortality, 26.05 per cent. (166 deaths).

(*b*) Tracheotomy in 20 cases; mortality, 45 per cent. (9 deaths).

(*c*) Intubation and tracheotomy in 11 cases; mortality, 63.63 per cent. (7 deaths).

Number of States represented, twenty-two, the District of Columbia, and Canada.

Non-operated cases, 1036—60.79 per cent. of all cases; mortality, 17.18 per cent. (178 deaths).

Operated cases, 668, or 39.21 per cent. of all cases; mortality, 27.24 per cent. (182 deaths). Two facts may be recalled in connection with this paragraph. (1) That before the use of antitoxin it was estimated that 90 per cent. of laryngeal diphtheria cases required operation, whereas now, with the use of antitoxin, 39.21 per cent. require it. (2) That the percentage figures have been reversed, formerly 27 per cent. approximately representing the recoveries, whereas now, under antitoxin treatment, 27 represents the mortality. To put it in other words, before the use of antitoxin, 27 per cent. recovered; now 73 per cent. recover, and this in the severest type of diphtheria.

The present report will strike many members of the Society as revealing a mortality too large in each of the two classes. The mortality is large—larger than the personal experience in private practice of many would expect.

The reasons for this are (1) that antitoxin is still used too late, either from procrastination on the part of the physician, or objection on the part of the friends, or (2) in a half-hearted way, which shows itself in doses from one-tenth to one-fourth as large as they should be. In truth, both the physicians and the friends of the patient are timid.

This report, it must be admitted, shows too large a mortality. In the opinion of the Committee it is a larger mortality than will ever be shown again. Antitoxin is gradually being used earlier in the disease, and it will soon be used in sufficient doses.

To the Society, the Committee desires to say that it has sought to carry out their wishes in putting antitoxin on trial, to accept no testimony that did not bear the stamp of reliability, that it has employed the methods approved in the case of the first investigation and report, and that it has confined its work to definitely answering the main questions which the Society and profession now have in mind. Points that were settled in the first report and have since been corroborated by general medical literature are not again taken up.

If the Committee is asked to put forth the three most valuable points established in this eleven-months' work, they are:

1. The mortality of laryngeal diphtheria at present rests at 21.12 per cent.

2. That 60 per cent., approximately, have not required intubation.

3. That the mortality of operated cases is at present 27.24 per cent.

(Signed) W. P. Northrup, M.D.
Joseph O'Dwyer, M.D.
L. Emmett Holt, M.D.
Samuel S. Adams, M.D.

THE COMMITTEE RECOMMENDS:

Antitoxin should be given at the earliest possible moment in all cases of suspected diphtheria.

Quality.—Of the products on the market some have, by test, been found to contain one-half to one-third the antitoxin units stated on the label. Select the most concentrated strength of an absolutely reliable preparation.

Dosage.—All cases of laryngeal diphtheria, the patient being two years of age or over, should receive as follows:

First dose—2000 units at the earliest possible moment.

Second dose—2000 units, twelve to eighteen hours after the first dose if there is no improvement in symptoms.

Third dose—2000 units, twenty-four hours after the second dose, if there is still no improvement in symptoms.

Patients under two years of age should receive 1000 to 1500 units, the doses to be repeated as above.

CLINICAL MEMORANDUM.

ADHERENT PREPUCE AS A CAUSE OF CONVULSIONS IN CHILDREN.

BY J. HERBERT DAREY, M.D.,
OF NORTHWOOD, IOWA.

DURING the past year I have met with three cases of stupor and convulsions in male children, to which no other cause could be assigned than the presence of a prepuce adherent to the glans penis. All of the patients were promptly relieved by operation. These cases have strongly impressed me with the importance of a careful and thorough examination of the prepuce and glans penis in all cases of convulsions occurring in male children, when all other possible causes of reflex irritation have been eliminated.

CASE I.—Seen in consultation with Dr. D. S. More of Northwood, March 18, 1896. The patient, aged two years, had been under observation for a week or ten days, and during this time had been in a condition of stupor, from which he could be aroused only with difficulty, and into which he would immediately relapse after having been shaken. His head was normal in size, and no symptoms of brain pressure were present. The pupils were normal, and reacted readily to light. There was no trouble with his dentition. Micturition was very frequent. Anthelmintics and purgatives had been administered, with negative results. The foreskin at the meatus was red and irritated, and on passing a probe beneath it adhesions were found between its under surface and the glans.

The prepuce was divided and the adhesions separated, but as the former was not unduly elongated, circumcision was not performed. The wound was dressed with iodoform gauze soaked in carbolized oil, and the patient was put on drop doses of aconite, as his temperature varied from 102° to 104° F. The results were all that could be desired. The wound quickly healed, and in a few days he rallied from his condition of stupor, his temperature dropped to normal, and he has been well ever since.

CASE II.—This patient was also seen in consultation with Dr. More, on April 4, 1896. He was ten months of age, and had had a great number of convulsions, which had been considered epileptic. The father of the patient had had epileptic convulsions when a child, but had been cured. No cause could be found for the convulsions in our patient except an adherent prepuce. Circumcision had been performed by another physician, but the convulsions continued. When I was called in, his condition was such that he could be controlled only by the free administration of chloroform. He was put on bromids, and Dr. More subsequently prescribed a preparation of passiflora. He gradually improved, and is now strong and healthy, and has not had convulsions for some months.

CASE III.—This patient, aged two years and one month, was strong and healthy, and of good healthy parentage, there not being a trace of neurotic history in either parent. He had one severe convulsion last summer, which was attributed to an overloading of the stomach and bowels. On January 11, 1897, he was taken with a severe convulsion, which lasted upward of three-quarters of an hour. I put him on large doses of bromids, at once. The same evening his temperature rose to 103° F., and it was only by the constant use of chloroform for a considerable period of time that he was kept from going into other convulsions. I gave him two grains of acetanelid and tincture of aconite in drop doses, every hour, to reduce his temperature, but, in spite of this treatment, his temperature steadily rose to 105° F. I then put him in a wet pack, which speedily reduced his temperature a couple of degrees. It began to rise again rapidly, however, and he was extremely restless and nervous. I now put him in a tub of water at a temperature of about 90° F., gradually reducing the bath to 70° F., by the addition of cold water. I left him in the bath until he began to shiver, and goose-flesh was well developed all over his body. He was then taken out, rubbed dry, and rolled up in flannel blankets. His temperature was reduced to 101° F., and he had a sound, refreshing sleep. The next day he was much quieter and free from nervousness, but toward night he became very restless again, and his temperature rose steadily, but not to such a high point as before. The bromids and aconite controlled the condition sufficiently, and it was not necessary to resort to the cold bath. Next day he began to grow worse again, and I examined his penis to see if I could find any source of irritation there. The prepuce was red and angry-looking, and on inserting a probe I found adhesions. I advised circumcision as the only means of relieving the reflex source of irritation and stopping the convulsions. This was readily acceded to by the parents; so I operated at once. The inner surface of the prepuce was universally adherent to the glans penis, and had to be dissected off, bit by bit. The wound healed nicely, and the patient began to improve rapidly and to gain flesh. He has had no return of anything approaching convulsions since.

MEDICAL PROGRESS.

The Causes of Cancer of the Uterus and Its Best Treatment.—In the *Archiv. de Gyn.*, Vol. liii., p. 47, 1897, Backer reports his investigations of the 705 cases of carcinoma of the uterus treated in the University Clinic at Budapest from 1882 to 1895. From the study of this extensive material he attempts to answer three questions: (1) "Is the cause of carcinoma of the uterus of such a nature that one can speak of prophylactic treatment?" (2) "What are its initial symptoms?" (3) "Which is the best operation, and what results may be expected?"

From the most careful study of the cases, with reference to their age, marriage, number of children, etc., the author concludes, in answer to the first question, that as yet there is no known definite cause of carcinoma. There is no ground to believe it to be due to a micro-organism.

The clinical cause which, in a certain way, prepares the tissues for carcinoma of the uterus is endometritis, whose beginning, in most cases, dates from confinement. This statement rests upon certain facts shown by his statistics, as follows:

(*a*) Carcinomatous patients have borne more children than non-carcinomatous patients, but the carcinomatous trouble, in most cases, occurs not immediately after birth, but after a lapse of some years.

(*b*) Not every chronic endometritis favors the development of carcinoma, but an endometritis of a particular type, namely, a puerperal type. The proof of this lies in the relative freedom from carcinoma of sterile women and those women who suffer from gonorrheal endometritis.

(*c*) In almost every case of uterine carcinoma there is a chronic catarrh.

(*d*) The disease occurs much oftener in married women and widows than in single women.

(*e*) Carcinoma of the uterus occurs more frequently among the poor than among the rich, and the former are much more apt to allow a leucorrhea to run on untreated.

(*f*) This opinion of the predisposition of inflammatory processes is recognized in relation to carcinoma elsewhere in the body; for example, in the breast, stomach, etc.

In answer to the second question, Bäcker calls attention to two symptoms, the importance of which, in the early diagnosis of carcinoma uteri, has been somewhat overlooked. One of these is the occurrence, very early in the disease, of disturbances of the bladder, consisting usually of frequency and urgency of micturition.

The other symptom has reference to the consistence of carcinomatous tissue. This is hard, but brittle, while chronic endometritis produces a tissue which is hard and tough. If the carcinoma, therefore, begins in the vaginal portion of the uterus, a tenaculum easily tears out of it, which it will not do out of a chronically inflamed cervix. Carcinomatous tissue is easily curettable, while the tissue of chronic inflammation is more resistant.

With reference to the operation presenting the best prognosis, Bäcker declares himself heartily in favor of vaginal hysterectomy. He admits that the high amputation advocated by Schroeder has a slightly smaller mortality—an advantage which is completely over-balanced by the fact that "a recurrence is more likely to follow this operation than that of total extirpation of the uterus. The author expresses himself as strongly against any radical operation in cases where the disease has progressed beyond the uterus itself.

THERAPEUTIC NOTES.

A Gargle for Follicular Tonsillitis.—Levy (*Journ. de Méd. de Paris*, March 14, 1897) recommends the following as a gargle for tonsillitis:

℞	Beechwood creasote	. . .	gtt. viii.
	Tincture of myrrh	aa. . .	oz. ij.
	Glycerin		
	Water	. . . . . .	oz. iv.

A Remedy for Excessive Perspiration.—In cases of excessive perspiration Krahn (*Therapeut. Monatsch.*, March, 1897) recommends the use of the tincture of salvia, twenty drops in the morning and from twenty to forty drops in the evening. It must be taken continuously for several weeks in order to obtain a permanent cure. Unfortunately this old, harmless, and cheap remedy, like many others of its class, is unknown to the present generation of physicians.

Holocain; a New Anesthetic.—Gutmann (*Deutsche Med. Wochen.*, March 11, 1897) describes the advantages and disadvantages of a new local anesthetic known as holocaïn, a drug which is soluble to the extent of 2.5 per cent. A solution of the hydrochlorate of a strength of one per cent. is bitter, of neutral reaction, and is unchanged by boiling. Three or four drops of this solution produced anesthesia in the eye of a rabbit in from one-half to two minutes, which lasted about ten minutes. Its action in the human eye is similar. Its advantages over cocain are that it more quickly produces anesthesia, and that while dilatation of the pupil often continues for twenty-four hours after the use of cocain, holocaïn has no such action. Unfortunately the subcutaneous injection of this drug is dangerous; and another disadvantage in connection with its use is the fact that it can only be sterilized in glass which does not contain alkali, otherwise numerous fine crystals are precipitated.

The Treatment of Puritus Ani.—Brocq (*Journ. de Méd. de Paris*, March 14, 1897) recommends the following treatment for itching of the anus: The patient is to apply first a soothing ointment of vaselin and oxid of zinc, and then a large quantity of the following powder, which is kept in position by absorbent cotton.

℞	Powdered camphor	. . .	2 parts.
	Oxid of zinc	. . . . .	30 parts.
	Subnitrate of bismuth	. . .	30 parts.
	Chalk	. . . . . .	40 parts.

Frequent baths with borated water or tar soap are advisable, and the introduction at night of a suppository of cocoa butter containing cocain and extract of belladonna is often a useful addition to the treatment.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, MAY 15, 1897.

THE SUPERVISION OF PROSTITUTES AND THE CONTROL OF VENEREAL DISEASES.

No question is of more vital importance in the preservation and development of the human race than the control, restraint, and suppression of venereal diseases. It is so involved, however, in moral and social, as well as physiological, problems that it has ever presented most formidable obstacles to its solution. But as the chemical rays of the all-seeing sun are the best purifiers of an infected and polluted atmosphere, so is the daylight of intelligence the best clarifier of the noisome and reeking atmosphere of the social and physiological problem under discussion. Just now the British Government is interesting itself in the best method of controlling venereal diseases among the British troops in India, and much is to be learned from the information thus presented and its bearing upon the general question. According to the report of the Departmental Committee of the India Office recently submitted, there has been an alarming increase in the number of soldiers affected with venereal diseases, particularly syphilis. This subject has been the cause of a great amount of bitter discussion lately in both the medical and lay press of England, and in order to properly understand it, it is necessary to review the events of the past ten years.

A cantonment is a camp area within which troops are quartered, and which is under the special police and magisterial control of an officer commonly called the "bazaar master." He exercises certain summary powers over the residents of the cantonment, including the bazaar where the natives reside who minister to the wants of the military and their camp followers.

The so-called Indian Contagious Diseases Acts granted the bazaar master control over the prostitutes residing in the cantonment. They were regularly inspected, were forbidden to practise their profession except in certain recognized houses, and if found to be suffering from any communicable venereal trouble, were cared for in the hospitals provided. On the other hand the soldiers were forbidden to have intercourse with any unlicensed women, and if they were found suffering from gonorrhea or syphilis, an investigation was made to discover its origin. The soldier of course was treated and if it was found that he had contracted the disease "out of bounds" there was punishment as well as medicine awaiting him.

The opponents of these regulations based their objections to them chiefly on the grounds that the Government was encouraging immorality by supplying the men with prostitutes; and so much popular feeling along this line developed that in 1888 by a vote in the House of Commons the government of India was denied power to frame police or sanitary regulations regarding venereal diseases in cantonment areas.

Since that time matters have not improved, and during the last few years there has been an alarming increase in the number of men incapacitated on account of these maladies. The Army Medical Report for 1895 in reference to this subject stated that there were constantly sick from all venereal diseases taken together, more than 3000 out of the 70,000 British troops in India; while the indirect effects in the way of broken-down health, and dissemination of disease throughout England by returning soldiers was incalculable.

Last November the India Office appointed a departmental committee to investigate the whole subject; and the report of this committee, made public March 20th, arraigns in the most scathing terms the present policy of the government.

"The present condition of the army in India, yearly sending home thousands of men infected with constitutional taint, is a great and growing source of danger to the whole community. The influence it is liable to exert upon the health of the home population is one of the gravest aspects of the whole question. . . . Among 5882 men detailed for field service with the Chitral Relief Force, 462, or nearly eight per cent., had to be rejected, owing to disease; 279 more, or an additional four and a half per cent., had to be transferred from the field hospitals to the base. According to this ratio, 8800 men, out of a total force of 71,031 British soldiers in India, would have to be put down as useless. . . .

"It is known that among the majority of European armies special regulations are enforced in combating venereal disease. The British army in India is an exception. The ratio per 1000 strength of men incapacitated in the German army is 27.3; in the Russian, 43; in the French, 43.8. What is the ratio in our own army? It is 203.7 at home and 438.1 in India. Comment is surely superfluous. This deplorable state of things does not appear to be attributable to general causes, but to one cause alone, namely, the sexual act. Drunkenness and crime have greatly diminished. More care than ever is taken of soldiers in the way of recreation, cleanliness, and the encouragement of athletic and manly sports. The hard fact remains that among a body of men, mostly very young, and nearly all obliged by the conditions of the service to remain unmarried, only a few can resist such temptations as are offered to them, with the results that have been hinted at in the preceding paragraphs."

In Netley Hospital, to which the soldiers are assigned upon their return from India, the report says that "out of 263 cases, 196, or seventy-four per cent., had a history of syphilis. Never have so many or so bad cases of this disease been sent home as during the last five years. . . . Not a few are time-expired, but cannot be discharged in their present condition, incapacitated as they are to earn their livelihood, and in a condition so repulsive that they could not mix with their fellow-men. . . . They remain at Netley, in increasing numbers, which, as matters now are, seem likely to continue to increase."

Even in the light of these terrible disclosures, opinion is divided as to the course the Government ought to pursue, and there will evidently be bitter opposition on the part of medical men as well as others to the reestablishment of the Contagious Diseases Act either in their previous or any other form. Aside from the sentimental objection already referred to, it is claimed that in this case protection does not protect. Not only in the English army during the period when there was official regulation was there far too much venereal disease, but at the present time in France and Germany, where police license and inspection is more thorough, the number of civilians and military who contract disease is sufficiently great to give the opponents of the Act a very good supply of ammunition. They quote a number of recognized authorities to prove the unreliability of the most thorough inspection of prostitutes. Potten for instance says that, at least five times out of six, soldiers contract syphilis from registered and periodically inspected women; and Diday records a case in which the son of an eminent statesman contracted the disease from a highly placed courtesan whom he had pronounced free from every taint after a most thorough examination made by himself at her request.

The trouble with this testimony, however, as appears at first glance, is that it offers no comparison with what would have taken place without any inspection. It is as if a man built a roof of leaky boards, and his neighbor urged him to remove it on the ground that it allowed much water to come through, forgetting that for every pint which finds its way between the chinks some gallons are tumbled off onto the ground. Of course, if the neighbor had an absolutely water-tight roof to offer, that would be another story. In the present instance, the opponents of the Contagious Diseases Act have apparently nothing better to advocate. What seems like a way out of the difficulty, and some suggestions which are applicable to the general question will be given in a later editorial.

THE FINAL ANTITOXIN REPORT.

In another column of this issue may be found the supplementary and final report of the committee appointed by the American Pediatric Association to investigate the efficiency of diphtheria antitoxin. The conclusions deduced by this committee have been sanctioned by the Association and are now given to the world with the full weight of its approval and authority. But that the most critical skeptic shall be disarmed, the methods of this investigation have also been presented in detail.

The solution of two crucial questions has been undertaken. Upon the answers given the claims of antitoxin have been allowed to stand or fall: "(1) What percentage of cases of laryngeal diphtheria recover without operation under antitoxin treatment? (2) What percentage of cases subjected to operation recover?"

It is proven by the committee's report that in eighty-two per cent. of non-operated cases the patients recovered under the serum treatment, the average percentage of recoveries in the pre-antitoxin period being ten per cent. To apply even a severer test, let us take the children under two years of age, in which class of patients laryngeal diphtheria is confessedly so dangerous that a mortality approximating one hundred per cent. was formerly regarded as not unusual. Under antitoxin in 356 of these cases only 102 patients were lost, a mortality of less than thirty per cent. With no other evidence than is contained in this statement the most stubborn objector must be convinced.

The investigation of operated cases is equally gratifying; nearly seventy-three per cent. recovered.

A most encouraging feature developed by the committee, but not mentioned in its report, is the fact that 1700 cases of laryngeal croup were treated with the remedy during eleven months. This goes to show how strong a hold serumtherapy has taken upon the minds of earnest physicians throughout America.

A very practical suggestion is offered by the committee when a sufficiently potent dose is recommended. As with all untried remedies, the early use of diphtheria antitoxin was very properly tempered by a spirit of caution, but since a purer and more concentrated product is now furnished, experience would suggest a larger and more efficient dosage.

The highest commendation should be accorded the American Pediatric Association for so peristently adding line upon line and precept upon precept until a verdict of *proved* has been established beyond peradventure. The final word has been spoken—a fact is before us.

ECHOES AND NEWS.

The American Climatological Association.—The following officers have been elected for 1898: President, Dr. E. O. Otis, Boston; Vice-presidents, Dr. Beverly Robinson New York, and Dr. C. F. McGahan, Aiken, S. C.; secretary and treasurer, Dr. Guy Hinsdale, Philadelphia. The next meeting will be held in the White Mountains, New Hampshire, in 1898.

The New Hampshire State Medical Society.—This Society will hold its one hundred and sixth annual meeting at Concord, May 24 and 25, 1897.

Wearing of Corsets Forbidden.—A fact worth recording is that the female employees of many German factories are forbidden to wear corsets during working hours.

The Prevalence of Diabetes.—The statistics of this disease show that it is steadily and rapidly increasing in all the great cities of Europe. This is another of the penalties of advanced civilization.

California State Medical Association.—At the meeting of this flourishing organization, at San Francisco, on April 22d, Dr. C. L. Bard of Ventura was unanimously elected president for the ensuing year.

The American Medical Editors Association—This Association will hold its next regular annual meeting at the Aldine Hotel, Philadelphia, June 1st. The dinner will occur at the same place in the evening of the same day.

British Charity in Jubilee Year.—The Prince of Wales' hospital fund was confidently expected to reach the magnificent total of £3,000,000, which would just cover, in the income it would produce, the annual deficit of the London hospitals. No figures have yet been printed, but there is no longer any talk of millions. There is doubt if £250,000 will be raised.

Membership in the American Medical Association.—There still seems to be some misunderstanding as to the proper means of becoming a member of the American Medical Association. The rules of the American Medical Association show that each person who expects recognition should come armed with a certificate of membership in his State or County society. No person presenting himself for registration will be accepted if he has not such a certificate.

The Wisdom of Government Officials. — The *Press and Circular* records that Mr. Hankin recently left Bombay, the seat of the plague—for Agra, taking with him all his bacteriologic specimens of the disease, and a certain number of mice for experimental purposes. No sooner was his arrival announced than a government official was sent to him with orders to seize all his specimens and burn them, and everything was ruthlessly cremated. How wise are the ways of some officials!

Alleged Drug Counterfeiters Detected.—It is reported from Chicago that the grand jury has indicted three men, one of them a physician of that city, on the charge of conspiracy, counterfeiting labels, and obtaining money under false pretenses in connection with the manufacture and sale of bogus drugs. The remedy counterfeited is made in Paris. The bottles were obtained through one Dumont. Over twenty Chicago druggists are implicated, and sensational developments are expected.

Notes Concerning the British Medical Association.—Dr. Charles Richet has been nominated as the official representative of the Faculty of Medicine of Paris at the Montreal meeting.—During the past week most of the American invitations have been sent out and received.—The citizens of Montreal are planning most liberal entertainment for the Association and its guests.—The New England Traffic Association offers to guests of the Association the usual reduction in railroad fares upon presentation of certificates.

A May Vaccination Bee.—The Italian mothers believe that May is the best time to have their children vaccinated. Accordingly, there were 1500 mothers carrying babies in their arms, and about a thousand children clinging to their mother's skirts assembled at the office of the New York Board of Health one day last week. Five doctors were busy all day in the free vaccinating bureau, but they succeeded in vaccinating only 620 babies. During the week the staff vaccinated over three thousand children.

Mr. Lawson Tait Ill.—It is reported that Mr. Tait, while operating upon a patient April 12th, was seized with violent pain in the neck of the bladder, followed by dribbling of urine. The symptoms were found to be due to an impacted calculus. A perineal incision was made and the calculus reached and successful removed. The operation was performed by Mr. Gilbert Barling, assisted by Mr. Christopher Martin. With the exception of some depression, due to the severe and protracted pain, Mr. Tait is making a speedy recovery.

The Medical College of Alabama.—The annual commencement of the Medical College of Alabama took place at Mobile on the evening of April 9th, and was of particular interest from the fact that the union between this institution and the University of Alabama was then formally ratified. The university has had a long and honorable career, having been founded in 1827, and the college, which was organized in 1860, numbers many of the most eminent practitioners of the South among its alumni. This union of forces will redound to the advantage and usefulness of both, and is another indication of the general trend of effort in different portions of the country to concentrate means and abilities toward the attainment of higher education.

Infection from Public Baths.—Professor Baginsky has been investigating the condition of the water in some of the public baths of Berlin, and has found a very large increase in the number of bacteria after a considerable number of people had bathed. After twelve hours, when two hundred persons had used the bath, the water contained 90,000 germs per cubic centimeter; while, after twenty-four hours, when 549 persons had bathed, the germs amounted to 270,000 per cubic centimeter. The microbes found showed the filthy nature of the pollution, and were suggestive of the danger of acquiring typhoid fever by the swimmers swallowing any of the water. This emphasizes the superiority of the spray or douch bath for a working-class community.

The Medical Sentinel, Dr. Kiernan, and the Virginia Medical Semi-Monthly.—*The Virginia Medical Semi-Monthly*, in a recent issue gives the MEDICAL NEWS credit for having said that Dr. J. B. Kiernan, of Chicago, had recently severed his editorial connection with the *Medical Sentinal*. The *Medical Sentinel*, and there is no other medical journal by this name in the world, is published at Portland, Ore., and is now in its fifth year. As the editor, Dr. Henry W. Coe is also its owner, it is safe to say that there has been no conflict between editorial and other departments, relative to the policy of that journal. Dr. Kiernan has never had any connection, editorial or otherwise, with the *Medical Sentinel*, and Editor Edwards has gotten things mixed by quoting the MEDICAL NEWS in the manner he did.

Professor Charles F. Chandler Resigns.—Professor Chandler has resigned his positions as Professor of Chemistry in the College of Physicians and Surgeons of New York and as Dean of the School of Mines of Columbia University. His reason for giving up the two positions is that he may be able to devote his whole time to the professorship of chemistry at Columbia. At the close of Professor Chandler's farewell lecture to the students of chemistry at the College of Physicians and Surgeons, May 7th, a testimonial of the esteem in which he is held by the students was given him in the shape of a loving-cup, subscribed for by those who have attended his lectures. The professor's desk was covered with roses, and the platform had also been ornamented with flags and other decorations.

Bulletin of the Iowa State Board of Health.—The Iowa Board of Health deals out advice on health topics in a truly paternal manner. "Spring is here," the board says in a recent bulletin, "and soon the flies will be on hand and demand house-room and feed." They should be given neither. They come from filthy places with their legs covered with morbific matter "and crawl over the bread and sugar and fruit and cake and pie," depositing thereon bacteria of the most poisonous kind. Therefore, in the words of the board, "decency and a due respect for health suggest that money spent for screens, for doors and windows, and for sticky fly-paper is money well spent." Another spring suggestion by the board is the eating of lemons, for therapeutic, esthetic, and sanitary reasons. On this point the board makes an ingenious appeal to the women. "Scarcely anything is better for the complexion," it says, "than a good healthy action of the liver and stomach." Summed up, the advice of the board to women is to discard veils and buy lemons.—*New York Times.*

Cooking Schools for Marine Cooks.—The suffering caused by scurvy among the crew of the ship T. F. Oakes, which recently arrived in this port, calls attention to the establishment in England of cookery schools, devoted exclusively to the training of marine cooks. A. Quinlan, instructor of the Seaman Cookery School of Liverpool, refers, in a recent communication to the *Epicure*, to the fact that on ships provided with certificated graduates from the institution named no cases of scurvy ever occur. The pupils are taught how to make fresh food out of the saltest of meats, and to concoct appetizing dishes from all sorts of ship's stores. Mr. Quinlan instances the case of the ship Holt's Hill, which carried one of his certificated cooks. This vessel made a voyage around the world, and not a single case of illness occurred among the crew. Usually on English ships that make long voyages desertions are many on account of insufficient and improperly prepared food; but on the Holt's Hill the original crew remained from the beginning to the end of the voyage. This is looked upon as a phenomenal record.

Annual Commencement of the Medical Department of the New York University.—At the fifty-sixth annual commencement of the Medical Department of the New York University, held in Carnegie Hall, May 4th, Chancellor MacCracken made an announcement about the combined University Bellevue Hospital School of Medicine, which, he said, would be open October 2d. The faculty will be appointed next week or the week after. The new handbook will be published about June 1st, and will contain full information about new buildings and new appliances for the reorganized school. The Mott medals were awarded as follows: Gold medal, C. F. S. Whitney; silver, Ralph J. Hess; bronze, Aaron Denenholz. The first money prize of $200 was won by John Howland; the second, $100, by E. N. Bowen; the third, $50, by Isaac Zarch. The honor men were named in the following order: John Howland, E. N. Bowen, Isaac Zarch, S. T. Quinn and J. J. Moorehead. The prizes in the competitive examinations for hospital appointments were awarded to B. L. Wilson, J. J. Nutt, S. D. Dice, A. H. Mandell, Jr., P. B. Davenport and T. E. Berry. Other hospital appointments were awarded to T. B. Barrington, Jr., L. V. Waldron, Frederick Rustin, John Howland, F. J. Tooker, A. S. Englehart, W. M Stone, W. G. Schoonmaker, D. L. Morrison, Stewart Lewis, E. N. Bowen, M. I. Blank, L. Harris, W. M. Spitzer, H. H. Wilson, and William Menger.

CORRESPONDENCE.

STERCORIN VERSUS KOPROSTERIN.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In the NEWS for May 1st, R. H. Chittenden, Ph.D., of New Haven, Professor of Physiological Chemistry in Yale University, in an article on "The Chemistry of Gall-Stones, with Special Reference to their Mode of Origin," read before the New York Academy of Medicine, April 15, 1897, says:

"As just stated, cholesterin is not readily decomposed, but in the case of man, according to the recent experiments of Bondzynski and Humnicki (*Uber das Schicksal des Cholesterins in thierischen Organismus, Zeitschr. f. physiol. Chem.* Band 22, p. 396), a portion of the substance undergoes modification in the intestine, appearing in the feces as koprosterin, a body closely related to cholesterin, and apparently formed from it by the addition of hydrogen."

In *The American Journal of the Medical Sciences* for October, 1862, is an article by me entitled "Experimental Researches into a New Excretory Function of the Liver, Consisting in the Removal of Cholesterin from the Blood, and its Discharge from the Body in the form of Stercorin." The sterecorin which I discovered in the feces in 1862 is identical with the "koprosterin" recently described. My methods for the extraction of stercorin from the human feces are practically identical with the methods recently employed in the extraction of "koprosterin." I proved that stercorin is derived from the cholesterin of the bile. Within the last few months I have repeated my observations of 1862, and have carried on side by side with them the manipulations employed by Bondzynski and Humnicki, with exactly the same results. I have compared specimens of "koprosterin" obtained by the recent methods with specimens of stercorin obtained in 1862, and have found the two substances identical.

While it is a matter of some surprise that Bondzynski and Humnicki should be ignorant of the existence of stercorin, it is a matter of greater surprise that an American physiological chemist, so prompt to accept observations made in Germany, should ignore stercorin, a name to be found in English, French, and German literature since 1862. Yours truly,

AUSTIN FLINT, M.D.

60 EAST 34TH ST., NEW YORK,
May 1, 1897.

OUR PHILADELPHIA LETTER.

From our Special Correspondent.]

THE INCREASE OF MALARIA—MEDICAL INSPECTORS FOR THE PUBLIC SCHOOLS—COMMENCEMENT AT THE JEFFERSON AND MEDICO-CHIRURGICAL COLLEGES—AMERICAN PUBLIC HEALTH ASSOCIATION—PHILADELPHIA COUNTY MEDICAL SOCIETY—THE SOCIAL SIDE OF THE AMERICAN MEDICAL ASSOCIATION'S MEETING.

PHILADELPHIA, May 8, 1897.

THE increasing prevalence of malarial fever in Philadelphia during the last year or two has occasioned no little comment among practitioners, as of recent years instances of paludism in this city have been more often the exception than the rule. The records of most of the large hospitals also bear witness to the growing frequency of this disease, and the fact that the increase in malaria has not been among those who have recently arrived here from malarious districts, but in natives of the city, argues against the importation of the disease by immigration, and demonstrates its local origin.

The sanitary condition of the Philadelphia public schools has, for a long time, been a subject of great dissatisfaction to those interested in the health of the community, and the deplorably unhealthy state of many of the school buildings, fully set forth in a recent official report on the subject, has actuated a movement led by Dr. W. W. Keen, to have the Board of Health insist on a daily medical inspection of the school children of this city, similar to that now in effect in New York and elsewhere. To get at the root of the evil by extensive reconstruction of many of the school buildings is, of course, too much to ask at present, so that Dr. Keen's suggestion, which will at least limit the spread of contagious diseases, should be made an important step forward in our municipal hygeine.

The commencement exercises of the Class of '97 of the Jefferson Medical College will be held on May 14th. Professor E. E. Montgomery will deliver the valedictory address, and there is also to be an oration to the class by Rev. Francis L. Patton, the president of Princeton University.

The graduating exercises of the present year's class at the Medico-Chirurgical College will take place on May 18th.

From a perusal of the preliminary announcement of the program of the meeting of the American Public Health Association to be held in this city on October 26th, 27th, 28th and 29th, it is evident that the coming meeting will prove one of the most important sessions ever held by the Association. Among the large number of topics listed for discussion the more prominent are those relating to the cause and prevention of infant mortality, to the pollution of water supplies, and to the subject of public health legislation, while an important consideration of the questions of the nomenclature of disease and forms of statistics is to be a leading feature of the meeting. Dr. Benjamin Lee, No. 1532 Pine street, Philadelphia, is the chairman of the local committee on arrangements.

At the stated meeting of the Philadelphia County Medical Society, held on April 28th, Dr. Orville Horwitz presented "An Inquiry into the Cause for the High Mortality Resulting from Suprapubic Cystotomy," in which he reviewed the statistics relating to this operative procedure, and showed that it was attended by a mortality which varied from thirteen to thirty-three per cent. Dr. Horwitz then quoted seventy cases, ranging in age from three to seventy-five years, upon which he had performed this operation, with but one death resulting, and dwelt particularly upon the proper preparation of the patient, and upon a perfect technic as important factors of a lower death rate. From his experience, he concluded that the high mortality in the hands of other operators was due, among other causes, to extensive and unnecessary dissection of the prevesical tissues; to injury to the peritoneum by the use of the knife after dividing the sheath of the recti muscles; to loss of time in exposing the bladder, after anesthesia had been effected, and a want of knowledge after exposure of the bladder as to whether the viscus was free from the peritoneal fold; and to over-distention of the bladder and of the rectal bag.

Dr. A. Graham Reed read a paper on "The Hot-Air Treatment for Rheumatism and Gout," and drew inferences concerning this means of therapeusis agreeing with the opinions already expressed before the Society by Drs. H. A. Hare and J. C. Wilson, the latter of whom, it will be remembered, long since introduced the treatment in this city, and has successfully and widely employed it in a large number of cases.

Aside from the scientific interests which attach to next month's meeting in this city of the American Medical Association, the visiting members will find that their time will be largely taken up with the numerous engagements of a social nature, which have been planned for their entertainment.

On the first day of the meeting, June 1st, they will be entertained at lunches given by the Philadelphia County Medical Society at the Hotel Walton; by the Laryngological Section, at the Howard Hospital; and by the trustees and faculty of the Philadelphia Polyclinic, at their hospital building. In the evening dinners will be given at the Hotel Walton by the Sections on Surgery and Anatomy, Diseases of Children, Neurology and Medical Jurisprudence, Materia Medica and Pharmacy, Dermatology and Syphilography, Obstetrics and Diseases of Women, and Ophthalmology, Laryngology, and Otology; and at the Aldine Hotel by the Section on Practice of Medicine.

On the second day, June 2d, there are to be lunches by the University of Pennsylvania, at Houston Hall, and by the publishers, The J. B. Lippincott Company, at the Union League Club. In the evening receptions will be given by the Jefferson Medical College, at the Academy of the Fine Arts; by the University of Pennsylvania, at the Union League Club; by the Medico-Chirurgical College, at the hospital of this institution; by the Women's Medical College, at their hospital; and by Dr. J. V. Shoemaker, at his residence.

On the third day of the session, June 3d, the following lunches will be given: By Dr. W. W. Keen, to the Surgical Section, at the Hotel Walton; by Dr. J. H. Musser, to the Section on Practice of Medicine, at Houston Hall; and by Dr. L. Webster Fox, to the Section on Ophthalmology, at the Hotel Bellevue. In the evening a large theatre party will be tendered the members of the Association by the medical publishing firm of Lea Brothers & Company.

On the fourth day, June 4th, the Philadelphia Medical Club will entertain the visitors at luncheon at the Aldine Hotel.

In addition to the above arrangements, a large number of Philadelphia clubs will keep open house for the visiting members, and the physicians of Atlantic City are making elaborate plans for the entertainment of those who are inclined to take the hour's ride to that seaside metropolis.

Vienna.

AN ENDEMIC HICCOUGH OCCURRING IN A YOUNG LADIES' SEMINARY — RESECTION OF THE GALL-BLADDER AND A PORTION OF THE LIVER FOR CARCINOMA—THE ANCIENT AND MODERN TREATMENT OF GOUT—REMARKABLE CASE OF HEMATEMESIS IN A HYSTERICAL WOMAN.

BERDACH reported to the Imperio-Royal Society of Physicians, at the session held March 12th, *an endemic hiccough occurring in a young ladies' seminary.* Sixteen out of the thirty-five scholars were attacked in one week.

The neurosis was undoubtedly of a hysterical nature. The first child attacked had well-marked symptoms of hysteria, and the second case was ushered in by a hystero-epileptic attack. According to Charcot, such attacks occur most frequently in anemic young girls, and are very apt to recur. The hiccough cannot be stopped voluntarily, but it ceases entirely in sleep. The children were at once removed from school, and seven recovered almost immediately. The prognosis in the other cases was thought to be good.

ULLMANN presented a patient from whom, six months previously, he had *removed the gall-bladder and a portion of the liver substance for carcinoma.* Although the resection was made with a Paquelin cautery the hemorrhage was troublesome, and was only stopped by suturing together the sides of the wound in the liver. This is the fourth case of carcinoma of the liver which has been treated surgically.

At the session of March 26th, **LORENZ** showed a number of patients to illustrate his *treatment of bony ankylosis of the hip-joint.* If the these cases are unilateral and the femur is ankylosed in a favorable position the patients can do very well without an operation. In those cases in which ankylosis has occurred with the limb in a bad position, or in which both sides are affected, Lorenz has performed with marked success linear osteotomy at the plane of ankylosis, following the operation with gymnastic treatment. In one young woman, aged twenty-two, absolute ankylosis had existed in both hip-joints. Locomotion was due before the operation only to a sort of tripping from the extreme points of the toes, made possible by the slight degree of motion in the symphysis, and the sacro-iliac synchrondroses. There had also been numerous attacks of osteomyelitis in various parts of the body. When the region of the joint was exposed it was found that its place had been taken, apparently, by a hugh bony tumor, so that a linear osteotomy alone would not suffice. Great masses of newly formed bone were removed and the surfaces of the femur and pelvis were separated. The wound healed promptly and gymnastic exercises were begun in six weeks. When presented, the patient possessed the ability to flex and extend the thigh through an arc of thirty degrees. Abduction was possible to fifteen degrees. In ordinary cases of linear osteotomy the patient should remain in bed not more than eight days, and should begin at once to go about with an apparatus devised for coxitis.

At the session of the College of Medicine, held March 15th, **STERNBERG** discussed the *ancient and modern treatment of gout.* As far back as Hippocrates moderation in quality and quantity of food was strongly urged. Upon this point, and this point alone, are clinicians to-day agreed. The treatment comprises four subjects, *viz.:* diet, alkalies, specific remedies, and mechanical therapeutics. Upon every one of these points opinions vary widely. Pfeifer recommends a purely meat diet. The French authors object to soup because meat extracts are poisonous to the kidneys. A milk diet is suitable in only a small number of cases, as many patients with gout bear it very badly. Some physicians forbid their patients to eat sour articles of food, while others recommend fruit cures (strawberries, cherries, etc.). All agree that alcohol is injurious.

Of the alkalies, lithia is not very soluble, and, moreover, it upsets the digestion and accomplishes little good. Von Noorden recently advised the use of calcium carbonate. The only objection to its use is the possible formation of intestinal concretions, and this can be overcome by the use of laxatives. The phosphoric acid which is abstracted from the urine by the calcium is eliminated in the intestine, and the sodium acid phosphate in the urine is increased by just that amount which favors the solution of uric acid. Instead of the already forgotten ammonium compounds, modern therapy has found similar preparations with amin bases; for example, urotropin and piperazin. All of these substances are irritating to the stomach.

In the discussion which followed the reading of this paper it was evident that the members of the society expect more benefit to follow treatment by baths of various kinds, friction of the skin, and massage, than from any internal remedies.

ZAPPERT presented to the Medical Club, March 10th, a case of *juvenile progressive paralysis* existing for two years in a girl aged thirteen. The trouble began with difficulty in walking, followed by psychic disturbances. The child suffered besides from hereditary syphilis. It has been recently shown that of forty-one cases of progressive paralysis eighty-seven per cent. were victims of hereditary syphilis.

At the session of March 24th **LEDERER** related the history of a *remarkable case of hematemesis in a hysterical woman,* who lost in the course of one month more than thirteen liters (quarts) of blood, five liters being lost in four days without producing unconsciousness. The hemorrhages occurred not only from the stomach, but also in the secretions and excretions, even in the secretions of the breasts. This woman had taken in the six months preceding these hemorrhages two hundred grams (seven ounces) of paraldehyde. It was suggested that this may have been the cause of the bleeding.

As a result of his researches, **HERZ** concludes that a *comparative insufficiency of the ileocecal valve* exists when, in the cadaver, it does not resist a pressure of at least twenty centimeters of water (eight inches). If the valve is well formed it will resist enough pressure to burst the colon. Incompetent valves are frequent in alcoholic subjects and those who suffer from diseases of the heart or chronic diseases of the large intestine. Upon the living, insufficiency of the valve can be demonstrated by pressing the edge of the left hand against the ascending colon, and squeezing the cecum with the right. If insufficiency exists, gas and fluids will be forced back into the ileum with a gurgle, and the percussion note over the cecum and ileum will be changed.

Constipation may be the result as well as the cause of the affection, because the large intestine empties itself more like the bladder than by peristaltic action, and if it communicates freely with the small intestine this action is greatly interfered with. Massage of the large intestine is more efficacious than purgatives and disinfectants, because it attacks the source of the trouble, while these are only palliative.

SINGER was inclined to doubt the possibility of making a diagnosis of incompetency of the ileocecal valve by palpation combined with percussion. He suggested insufflation of air as a better means of making the diagnosis.

SOCIETY PROCEEDINGS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Fourth Triennial Session, Held at Washington, D. C., May 4, 5, and 6, 1897.

[Specially reported for the MEDICAL NEWS.]

GENERAL SESSION.

(Continued from page 611.)

THIRD DAY—MAY 6TH.

THE meeting was held under the direction of the American Orthopedic Association. The subject for discussion was

DEFORMITIES OF THE HIP-JOINT, ESPECIALLY CONGENITAL DISLOCATIONS.

The first paper was read by DR. E. H. BRADFORD of Boston. He said that it will be satisfactory to the profession at large to learn that an affliction which for centuries has defied all surgical efforts may at last be regarded as curable under the efforts of scientific surgery. Without taking time to review the history of the subject, he said that the world was greatly indebted to the efforts of Hoffa and Lorenz. An accurate knowledge of the pathologic anatomy, fortunately now well understood, is important. The etiology, however, is not known, although it is clear that true congenital dislocation is an affection of intra-uterine life. It would seem that it is not, like harelip, a defect of development, but, like congenital clubfoot, a malposition of the bones, with resulting changes in the soft parts, The speaker then reviewed, with the the aid of diagrams thrown upon a screen, the various theories in regard to the etiology, pathology, diagnosis, and treatment, with results. The following conclusions were presented:

Congenital dislocation of the hip is a dislocation of the head of the femur upward occurring during intra-uterine life. A shallow triangular acetabulum results. A diminution of the angle between the neck and shaft takes place and a twisting of the neck. The capsule is altered by being stretched and thickened; it is first dilated in its upper portion, stretched across the acetabulum in the lower portion, and constricted at the rim of the acetabulum. The most important obstacle to reduction lies in the attachment of the capsule at one end to the ilium above and around the acetabulum and to the anterior surface of the femur, especially to the lesser trochanter. The shortened pelvic femoral muscles also offer a resistance to the reduction and with the contracted capsule will prevent reduction or cause relapse. Obstacles to the reduction also lie in the shape of the head and in the shallowness of the acetabulum. Traction in an outward direction cannot effect a cure. Traction in a strong abduction with downward pressure upon the head may bring about reduction. In children over two and under five—in some instances between five and seven—under an anesthetic, forcible reduction can be employed. This can be done only if the head of the femur is forced through the capsular neck into the acetabulum and only after the capsular attachments adducting and flexing the limb are thoroughly stretched. Successful reduction is always accompanied by an audible movement of the head of the femur into the capsule, and bandages and fixation apparatus are to be used to prevent relapse until the contracted tissues are sufficiently long and the pelvic trochanter muscles have regained their power to a sufficient extent that a a recurrence of dislocation is impossible. In patients older than seven and under fifteen, and in some cases between five and seven, an open incision is necessary for reduction of the dislocation. Subcutaneous incision is useless. The line of incision following the outer edge of the tensor vaginæ femoris is preferable. Inability to reduce the head is due to capsular attachments from the acetabulum and ilium to the femur which have not yet been divided or stretched. In adolescents or adults, where extension of altogether new bone takes place, operative reduction has not been successful. The use of corsets and traction splints may improve attitude, but cannot cure.

DISCUSSION.

DR. V. P. GIBNEY of New York in opening the discussion, expressed embarrassment at speaking on this subject in the presence of Dr. Bradford, who had given so lucid a demonstration. He desired, however, to say something about the ultimate results in the cases operated upon and those not operated upon. He had seen six or eight of these cases a year during the last decade or more, but only within the past six or seven years had he made any attempt to carry out methodical treatment. When the method of Hoffa was first introduced, he began using the appliances, and he thought he obtained some good results, but he had not had enough cases to warrant too positive statements in regard to the method. If the operation is to be undertaken, he thought that the preliminary stretching referred to by Dr. Bradford is very essential. Cases in which he had used it had turned out best. He had encountered less difficulty in getting the head of the bone into the acetabulum in these cases, and they had gotten well without suppuration. This unfortunate accident will occasionally occur. He was sure that even Lorenz, judging from his own reports, had met with suppuration in some cases. This has not led him to adopt another method, however, but he has modified the original one. He claims that by this non-bloody method, if he has not a sufficiently deep acetabulum, by causing the patient to walk on the limb early, the head of the femur will force itself into the acetabulum.

DR. HARRY M. SHERMAN of San Francisco spoke first of what he had himself seen Lorenz do by his operation for reposition. His recollection differed somewhat from what had been presented by the essayist, but he admitted that the difference may have arisen from improvements adopted by Lorenz since he saw him operate. He had thought that the incision was anterior to the line of the tensor vaginæ femoris. He stated that after the operation the limb was put up in plaster-of-Paris, in a flexed and strongly abducted position, and kept so for six weeks, portions of the plaster being now and then removed until at the end of six weeks the child was permitted to walk. Another point of importance in the Lorenz method is the fact that this operator never abandons a case, but applies massage and requires the patient to work in his gymnasium at the earliest moment that is safe.

The Congress then passed under the direction of the American Surgical Association, the subject for discussion being

THE CLASSIFICATION OF ACUTE GENERAL PERITONITIS: THE PROGNOSIS AND TREATMENT OF THE DIFFERENT VARIETIES.

The subject of

THE CLASSIFICATION OF ACUTE PERITONITIS

was presented in an exhaustive review of the various forms of the disease, classified according to etiology and pathology, and clinically, by Dr. N. SENN of Chicago. (An abstract of this paper was published in the last issue of the NEWS.)

The subject of

THE PROGNOSIS AND TREATMENT OF THE DIFFERENT VARIETIES OF PERITONITIS

was presented in a paper by DR. ROBERT ABBE of New York, which will appear in the next issue of the NEWS.

DR. ANDREW J. MCCOSH of New York then opened the discussion of the papers. He first expressed regret that Dr. Senn had not given a more practical and less elaborate classification of the disease, but admitted that such a classification was impossible if Dr. Senn was unable to give it. He then asked several questions regarding varieties of the disease which were close in resemblance.

In regard to prognosis, he had little to say, except to agree with Dr. Abbe, that the duration of the disease had much to do with the outcome of the case. Another factor is the varying resisting power of different patients. Age and habits are also important factors. Patients with a diseased liver or disabled kidneys are very susceptible to septic infection. All his patients that recovered were under thirty-five years of age, and he did not recollect a case of a patient over forty-five years old that had recovered. He thought it must be difficult to decide at the time of operation between those cases which need simple cleansing and those which need thorough irrigation. In some of the most virulent cases the evidences of septic infection are but little marked, whereas, in the milder cases, the evidences are sometimes much more decided. He thought it better at the time of operation to consider every case as one of the severest grade of the disease, and to so treat it. Therefore, if the best method of treating the peritoneal cavity is by irrigation, we should adopt that method in preference to swabbing or scrubbing. By the latter process the endothelium must be damaged, its vitality diminished, and its resistance to infection impaired. He believed in complete irrigation. A free incision should be made in these operations, the patient being turned upon the side and the intestines being entirely removed from the cavity. It is also of the greatest importance that the intestinal and peritoneal surfaces be kept hot. The coils of gut are received into the hands of assistants, and covered by towels which have been wrung out in water as hot as can be borne. Glassful after glassful of hot salt solution is poured over and through them at the same time that a large hose from a glass reservoir is pouring the same solution into the cavity. The irrigating fluid should be a sterile, normal, salt solution. It is of importance to let a certain amount of the same fluid remain behind in the peritoneal cavity. It acts as an immediate heart stimulant, and increases intestinal drainage and the passage of septic matter out of the abdominal cavity. The bactericidal power of the peritoneal fluid is increased by it. Of course, the peritoneal cavity should be thoroughly cleansed. It is important to remove as much of the septic material as possible, and to dilute what remains with the sterile fluid.

Another point of importance is in regard to the respective advantages of opium and of catharsis. There is an inclination at present toward the use of opium in full doses, and a tendency to discourage the use of cathartics. The speaker was entirely opposed to this change, however, and believed that treatment by opium was the worst that we could adopt in cases of general septic peritonitis. It is, of course, indicated in cases of idiopathic or local peritonitis, when we wish to confine the inflammation to a small area. He thought that every method should be employed to restore to the intestines their peristaltic action. Everything should be done to favor intestinal drainage, and to prevent distention and thinning of the walls of the gut and stagnation of blood, and to prevent the escape of the colon bacillus out of the intestine. Much difficulty arises here in the inability of the patients to retain cathartics. On this account the speaker had begun to administer various cathartic substances by means of intra-intestinal injections at a high point in the small intestine. He had become so convinced of the great value of this method that he now employs it in all his cases, injecting one to two ounces of a saturated solution of magnesium sulphate into the small intestine by means of a large antitoxin syringe, the puncture being closed by a Lembert suture. He remarked further that his results had been so much superior from this method that he was forced to conclude that the saline injection has had much to do with it.

He then presented statistics of the results which he had obtained by the use of this method. He showed that between the years 1887 and 1895 his mortality had been eighty-six per cent., whereas, since the adoption of the present method in 1896, he had operated upon nine cases, with six recoveries. He believed that the early movement of the bowels was an important factor in the recovery. In some of his successful cases the prognosis had been exceedingly grave, but improvement began almost immediately after the operation, the bowels moved early, flatus disappeared, and the patient went on to a speedy recovery.

Referring to the application of heat or cold to the external surface of the abdomen, the speaker said that neither was of value, as they cannot affect the temperature of the interior more than about half a degree. Cold is, however, grateful to the patient. Drainage is of great importance. A free incision should be made and the peritoneal cavity thoroughly drained. His preference was for gauze strips running in between the coils of the intestine. The glass tube is sometimes used in addition to the gauze strips, but rubber tubes are now very seldom used. He preferred chloroform as an anesthetic in these cases. In conclusion he insisted strongly upon early operation, thorough cleansing of the peritoneal cavity, and an early restoration of peristalsis.

DR. GEORGE R. FOWLER of Brooklyn, as his contribution to the discussion of the subject, next read a paper on

PERITONITIS CONSIDERED FROM THE CLINICAL STANDPOINT (SEE PAGE 627).

DR. J. T. JOHNSTON asked that Dr. McCosh give further particulars in regard to the injection of saturated solution of magnesium sulphate into the small intestine. If it has proved such a valuable means of hastening peristaltic action, he thought it desirable that the method should be fully understood.

DR. MCCOSH replied that he administered the dose during the operation, when the intestine was exposed, and repeated what he had already said in regard to location of puncture, syringe used, and closure of the puncture by Lembert suture.

DR. WILLIAM H. WELCH, Chairman, then remarked that the question as to the existence of a chemic peritonitis is a matter that has not been entirely settled. He agreed with Dr. Senn that we would better regard cases of general peritonitis as due to the action of micro-organisms.

There are certain points in regard to the distribution of peritonitis which are of importance. In some cases of intestinal ulceration there is a limited fibrinous exudate over the surface of the ulcer which does not contain micro-organisms. This fact is interpreted to mean that the micro-organisms are the cause of the peritonitis, but only by a chemic process through the toxins which they produce. But to exclude the presence of micro-organisms in the exudate, a very painstaking examination must be made. Not only cover-slip preparations should be examined, but cultures in every case, and if possible, animals should be inoculated. There is no question, however, of the occurrence of a very limited fibrinous exudate over the area without micro-organisms. Again, there may be quite a regular distribution of organisms in a localized peritonitis, patches of exudate appearing over a considerable area. One will sometimes find occasional bacteria in the pockets of pus, but no bacteria in the area around the pocket. The distribution of the exudate gives no guarantee of the distribution of bacteria, especially in the fibrinous and serofibrinous exudates.

DR. ROBERT ABBE desired to add a word in regard to the use of antitoxin in cases of peritonitis. Notwithstanding the excellent results that have been reported, he did not think that the records would show any real benefit from its use. He had used it in three cases with what he thought were injurious results.

DR. WILLIAM H. CARMAULT moved that a vote of thanks be tendered to the Cosmos Club of Washington City for its courtesy in extending to the Congress the freedom of the club rooms during the meeting and for the "smoker" to which the members had been invited.

DR. WELCH, in declaring the Congress closed, remarked that the registration had been very creditable, over five hundred having registered, and a very large number had attended the meetings who had not enrolled their names. The program had been especially full and rich, and the general discussions had been excellent. He felt that the plan which had been adopted in preparing the program was a success, and he expressed his personal thanks to those who had taken part. The Congress was then declared closed.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty Second Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

FIRST DAY—MAY 4TH.

(Continued from page 608.)

The President, JAMES R. CHADWICK, M.D., in the Chair.

THE HISTORY AND PRESENT STATUS OF HYSTERECTOMY FOR FIBROID TUMORS OF THE UTERUS.

DR. A. PALMER DUDLEY of New York, in continuing the discussion, referred to what had been said in the paper in regard to the influence of American surgery upon the methods of performing hysterectomy in other parts of the world, and said that two years ago a foreign surgeon had visited this country and attended a meeting of the Society. A year later the speaker visited him at his home and saw him operate, and noticed that he had changed his technic to conform to that of American surgeons. In regard to the menopause having a beneficial effect upon cases of fibroid of the uterus, this is a continuation of the old idea that the menopause is a cure-all. If such were the case, then Hegar's operation would be the ideal one.

DR. W. T. LUSK of New York thought that most of the members were agreed as to the proper treatment of fibroid tumors of the uterus, and that their apparent difference of opinion might be caused by the different types of cases which they see. Personally, he had seen a large number of insignificant fibroids of the uterus, whose presence had been discovered accidentally, and which gave rise to no symptoms. He sent such patients away, telling them to be examined once a year or whenever any symptoms appeared. Where operation is necessary, he was in favor of myomectomy. In some of these cases removal of the appendages had been followed by good results. He was glad to hear advocated the partial removal of the uterus, *i.e.*, leaving the cervix. The atrophy of the parts and sinking of the pelvic contents after total extirpation are often the cause of great discomfort.

DR. T. A. REAMY of Cincinnati thought that oophorectomy in the early stages often arrested the growth of uterine fibroids, but that it was illogical and unphysiologic to believe that the menopause, whether natural or artificial, could have a curative effect in the late stages. Observations made in the dead-house show that many woman, who died from various causes, have these tumors and were not conscious of the fact. In view of one fact, therefore, that a fibroid tumor often causes no symptoms and does not grow to a large size, he was in favor of conservative treatment. If symptoms appear at any time, operation can be resorted to when necessary.

DR. BEVERLY MCMONAGLE of San Francisco was in favor of both conservative and radical treatment of these cases, according to what was meant by the former term. Conservative treatment in a woman in the childbearing period would not be conservative treatment in a woman who has passed that stage. If an old woman has a fibroid tumor which, by reason of its weight or by the pain it causes, brings her to us, it is our duty to remove the tumor. If the patient has passed the menopause, hysterectomy seemed to him the best treatment; in younger women, the reproductive function should be preserved whenever possible, and any operation which prevents her from bearing children is a bad operation. For this reason he was opposed to oophorectomy in these cases. Myomectomy, he considered, was the operation indicated.

DR. GEORGE J. ENGELMAN of Boston considered the technic of the operation employed less important than the condition for which it was performed. Fibroid tumors are spoken of in a general way, as if they were all alike, whereas they differ very much in character. The vast majority of these tumors are not dangerous to life, but are perfectly harmless. They are frequently found in the dead-house in working women who never suspected their presence because they caused no symptoms. In regard to the arrest of development of a tumor by the establishment of the menopause, the speaker thought this rarely happened, and that, on the contrary, the condition generally became worse.

DR. THOMAS ADDIS EMMET of New York cited the case of a young woman in whom a fibroid tumor of the uterus disappeared during pregnancy, and was afterward felt on one side and was found to be attached to an ovarian tumor, showing that these tumors can be transplanted. He had always been conservative in the treatment of cases of fibroid tumor of the uterus, and was entirely opposed to removal of the uterus for this purpose. He thought hysterectomy had been done too often, and he never performs it if it can be avoided. In many cases he had removed large uterine tumors, piece by piece, through the uterine canal, and had also removed tumors of the broad ligament by entering the cavity between the bladder and the uterus. Now that the operation of hysterectomy had been so perfected, he hoped it would be performed less often, and that the profession would devote their attention to the genesis of fibroid tumors and endeavor to prevent their formation. He was convinced that they do not develop in women whose menstrual function is properly performed. A woman whose uterus is capable of making in its lining membrane a bed for a fecundated ovum, will never have a uterine fibroid.

DR. NOBLE, in closing, said he had several objects in view when he presented the paper, one of which was to point out the difference between true conservatism which considers the interest of the patient, and false conservatism which does nothing. Another was in regard to the fallacy that the advent of the menopause cures fibroids of the uterus. Twenty-five per cent. of his cases operated upon had passed the menopause. He had removed the appendages for the arrest of these growths and some of the cases did well, but the results of myomectomy are more satisfactory. He did not consider any operation conservative in which the tubes and ovaries were removed. He referred to what had been said about recurrence after myomectomy, and said the percentage was very low.

DR. H. J. GARRIGUES of New York then read a paper, entitled

SECONDARY OPERATIONS.

The author referred to the necessity of guarding against infection while operating and the tearing of the delicate peritoneal covering of the intestines and other viscera, which would cause the formation of adhesions and make a secondary operation necessary. He reported a number of cases to illustrate his statements, one of which was that of a woman who had been subjected to seven laparatomies and might have to undergo another.

DISCUSSION.

DR. A. LAPTHORN SMITH of Montreal regretted that the author had not given the indications for reopening the abdomen when things were not going on well. He cited a case in which he opened the abdomen of a patient who had had a previous laparotomy for ventral fixation of the uterus, and had found the fundus firmly adherent. All went well until the ninth day, when the patient refused food and began to vomit. The following day there was fecal vomiting, and the abdomen was reopened. The intestine above was found very much distended and collapsed below, and in one place had become adherent to a raw spot made by tearing away adhesions, and in this way caused obstruction. The patient recovered. The case served to show the importance of covering over all raw surfaces in the peritoneal cavity.

SECOND DAY—MAY 5th.

DR. ANDREW F. CURRIER of New York read a paper, entitled

SUGGESTIONS CONCERNING VENTRAL HERNIA RESULTING FROM ABDOMINAL SECTION, AND ITS TREATMENT.

He considered ventral herniæ under three headings: (1) *simple*, (2) *multiple*, and (3) *massive*. In the first variety there is a splitting apart of the muscular fibers, the peritoneum usually remaining intact and forming a sac which, with the abdominal contents, protrudes. The rent may gradually become larger, but there is no strangulation. The intestines in the sac become bound together, but the symptoms produced are usually very slight, being merely a feeling of discomfort. In the second variety the condition is more complicated. Separation of the muscular fibers takes place not only in the middle line, but in various parts of the abdominal wall, and generally occurs in women with weak, flabby tissues and much fat. This is the rarest variety of the three, and gives rise to many symptoms, and occasionally strangulation occurs. The third variety includes cases where the hernia is the size of a child's head or larger, and is usually a result of the smaller variety. To protect the parts, Nature throws out a fibrous ring around these herniæ at the border of the tear in the muscle, and the peritoneum becomes thickened. This variety gives rise to serious symptoms, and often becomes irreducible.

The author was of the opinion that all cases of ventral hernia should be operated upon as early as possible no matter to which variety they belonged and even when they caused but little discomfort. The old wound should be refreshened and the edges of the fascia brought together. In cases of long standing, the superfluous peritoneum should be removed. In cases where the abdominal tension is great, he advocates making longitudinal incisions through the fascia. Accumulations of fat should also be dissected out. Suture of the wound is a most important point, the object being to bring the edges of the tissues together and to hold them there until union is firm. He prefers silkworm gut to any other material for this purpose. Catgut was unsafe because of its liability to become infected, and the same can be said of silk. Silkworm gut sutures can be left in for three or four weeks, after which they either become loose or cause irritation. He employs a modification of the buried suture, because of the disadvantages of the latter, and introduces it as follows: Two curved needles are threaded on the ends of a strand of silkworm gut and both are introduced just above the angle of the wound from without inward, passing through peritoneum, fascia and muscle, and are then brought out and again inserted from above downward, and so on until the lower angle of the wound is reached, in the same manner as a shoe is laced. If the wound is not more than three inches in length, one suture is sufficient; if longer than this, a second suture should be inserted beginning at the lower angle of the wound and meeting the one from above at the middle of the wound. The skin is then united by a continuous suture of the same material. To protect the skin, a thin strip of gauze is passed under each suture. The superficial sutures are removed in two weeks and the deep ones two weeks later. The patient is kept in bed for a few days after the removal of the sutures and adhesive straps are worn to protect the wound for the next week or so.

DISCUSSION.

DR. J. M. BALDY said he had employed a silk suture for uniting the peritoneum and a similar one for the fascia and silkworm gut for the skin with excellent results.

DR. A. LAPTHORN SMITH urged the importance of leaving the sutures in for a long time. Hernia following operation had become very rare in his practice since he had adopted this plan.

DR. JOSEPH TABER JOHNSON thought that any method of closing an abdominal wound which would prevent ventral hernia should be hailed with delight. Most of the methods proposed, however, seemed very cumbersome and occupied a great deal of time, and thus necessitated a long anesthesia and caused additional shock to the patient. He thought that a series of through-and-through sutures, properly introduced and near enough together, embracing a good deal of the structures and drawn together with not too much force, would secure good union.

DR. A. P. DUDLEY said that the proper way to prevent hernia was to bring the edges of the linea alba together accurately. He did not think it was possible to get good union by over-lapping the ends of the fascia. He was also opposed to any suture method which included all the structures.

DR. CURRIER closed the discussion by saying he agreed with Dr. Johnson that any method of closing an abdominal wound properly and quickly would be desirable, but did not think that the method he recommended in the paper could be called cumbersome. It was necessary to use several rows of sutures because in most of the cases it is impossible to get good union with a through-and-through suture. The disadvantage of the buried suture is that after a month it causes irritation. As to the percentage of herniæ, occurring after operation, he thought this a difficult matter for a surgeon to decide for the cases did not always return to him when a hernia developed. Many cases of ventral hernia came to him who had been operated upon by other surgeons. The speaker emphasized the fact that all of these herniæ are not caused by imperfect technic.

THE PRESIDENT then read the annual address.

He said in part: Abdominal surgery in general is the outcome of ovariotomy, so that in its early days the history of the former is included in the history of the latter. For this reason, we Americans have an additional incentive in reiterating the indisputable fact that the first operation was done on our soil by one of our own countrymen. On the continent of Europe the operation had found but little favor. In Germany the first operation was performed by Chrysmar of Isny, Württemberg, in May, 1819; but from that year till 1850 but twenty-three operations were done, with only seven recoveries. In France there was no operation until that by Dr. Woyerkowsky in 1844, and but three (with two successes) up to 1850. In 1857 came the revival of ovariotomy, as it was called by Spencer Wells in the title of one of his retrospective papers, his participation in which earned for him the name of the "Greatest Ovariotomist." The secret of his success did not consist in any special procedure, but by attention to a multiplicity of details, which in the aggregate did a great deal to ensure recovery. Simple bandages for keeping the patient quiet supplied the place of an objectionable crowd of assistants. Every spectator had to declare that he had not made a *post-mortem* examination, or been in a dissecting-room, or attended a case of infectious disease within a week. The room, bedding, clothing, sponges, and instruments received the utmost attainable purification. The incision in the abdominal was shortened; the cyst was emptied before it was drawn out; extreme care was taken to prevent the entrance of ovarian fluid into the peritoneal cavity, and likewise to cleanse the cavity of all blood and fluid.

The final great innovation that has stimulated the practice of surgery was due to the discoveries of Louis Pasteur. Joseph Lister of Edinburgh first made a practical application of these studies of Pasteur and Lemaire. In 1867 he published a paper in the *Lancet* setting forth his crude methods of excluding germs from wounds. Of course it was at once seen by ovariotomists how vital this innovation of Lister's, if correct, would be in affecting the results of their work. Among the earliest to study Lister's methods was his fellow-townsman and friend, Thomas Keith.

The abdominal cavity was next invaded for the removal of fibroid tumors of the uterus. The earlier operations for this purpose were done when fibroids were erroneously taken for ovarian tumors.

So we find ourselves at the end of the nineteenth century with less reason to dread the opening of the abdominal cavity than our immediate predecessors had to dread even minor operations upon the body and limbs. The benefit of this advance to the individual and to the race is manifest; but I would beg you to pause a moment and consider with me if this operative mania has not gone too far—whether the time has not come when we must take an account of stock and differentiate more closely, in the individual cases, whether a removal of the whole or a part of the generative organs of a woman is the only method available for the cure of the diseases or injuries to which these organs are liable.

The natural menopause is attended with a prolonged derangement of the nervous system, not infrequently with impairment of the mental faculties. How much more pronounced are the ultimate effects of the menopause likely to be when the change of life is artificially produced when the nutrition and other functions are in full vigor. Of course, if the mishaps attendant upon childbirth and the diseases invading the sexual organs are incurable by other means than the surgeon's knife, exposure to the sequelæ of the menopause may be the lesser of the two evils; but let us not operate without an eye to the future as well as the present.

DR. EDWARD P. DAVIS of Philadelphia read a paper, entitled

PRIMARY TUBERCULOSIS OF THE BREAST COMPLICATING PREGNANCY,

which will appear in full in a later issue of the NEWS.

DISCUSSION.

DR. H. T. HANKS said that a similar case had come under his observation. When first seen, the patient was somewhat septic, and was supposed to be suffering from cancer of the breast. The latter was amputated, and the woman died three days later of sepsis. The pathologist reported it to be tuberculous mastitis.

DR. PAUL F. MUNDE read a paper, entitled

PERITYPHLITIS AND APPENDICITIS IN THEIR RELATIONS TO OBSTETRICS AND GYNECOLOGY.

(See page 621.)

DISCUSSION.

DR. W. E. FORD of Utica, N. Y., mentioned the case of a girl of sixteen upon whom he had operated for appendicitis. He evacuated the pus, but was unable to remove the appendix. The girl did well for a few days, and then became septic, so he operated again, thinking that another abscess was present, but found only a little pus at the bottom of the tract. Upon making a vaginal examination a large abscess was found, which had not existed at the time of the first operation, and more than a quart of pus was evacuated. There was no history of ovarian or tubal disease.

The speaker also reported a death from iodoform poisoning. He had been called to the country to operate upon a girl supposed to be suffering from appendicitis. No tumor was found in that locality, but an enormous abscess was found in the pelvic cavity, which was opened through the vagina, and two quarts of very offensive pus evacuated. After irrigating the cavity the speaker proceeded to pack it with iodoform gauze, and called the attention of his assistant to the bright yellow color of the gauze, but was assured that it was the ten-per-cent. gauze usually employed. About a yard of it was used. The temperature immediately fell after the operation, and the patient did well for several days, when a wild delirium came on without rise of temperature or other symptoms, and lasted until the patient died twelve hours later. The *post-mortem* showed no sepsis. The girl had a dilatation of the right side of the heart as a result of over-exertion in bicycling.

DR. A. LAPTHORN SMITH had frequently met with disease of the appendix while operating for pus-tubes, and in three instances had found the appendix apparent to the tube.

DR. R. A. MURRAY read a paper, entitled

THE TREATMENT OF SYPHILITIC WOMEN IN PREGNANCY AND PARTURITION,

which will appear in a later issue of THE NEWS.

DISCUSSION.

DR. EDWARD P. DAVIS confirmed all the views of the author, but thought in regard to the diagnosis of these cases that no examination was complete unless it included an examination of the genital tract. The predominant feature which makes syphilis dangerous during pregnancy is the anemia which accompanies it, and causes death of the fetus. Treatment, therefore, should be directed to this anemia, and iron and strychnia given in addition to anti-syphilitic treatment. He thought it questionable to allow a syphilitic mother to nurse her child. It should be fed on modified milk or other artificial food. He also referred to the fact that syphilis in pregnant women usually leaves behind it an endometritis.

DR. MURRAY, in closing, said that he did not mean to say that a syphilitic mother should nurse her child, but that no other woman should be allowed to nurse it.

DR. A. PALMER DUDLEY read a paper, entitled

SOME PATHOGNOMONIC PHYSICAL SIGNS OF CHRONIC GONORRHEAL INFECTION IN WOMEN, AND THEIR VALUE IN THE DIAGNOSIS OF PELVIC DISEASE.

THIRD DAY—MAY 6TH.

DR. THOMAS ADDIS EMMET of New York read a paper, entitled

WHEN TO AMPUTATE IN PREFERENCE TO THE USUAL OPERATION FOR LACERATIONS OF THE CERVIX UTERI.

The author emphasized the fact that amputation, as described in the paper, is in no way intended to replace trachelorrhaphy, but is to be employed in exceptional cases in which it is not possible to get a good result with the latter operation. The operation is indicated in cases of long standing in which the nutrition of the parts has become impaired, making it unfit to hold sutures, and in those cases where the laceration has been deep, involving more or less of the pelvic connective tissue and vaginal wall, and in which there is much scar tissue in the angles of the tear. He also laid stress upon the fact that amputation of the cervix alone in these cases is not sufficient, and that after-treatment, as well as preparatory treatment, should be employed. The operation advised is performed as follows: The uterus is drawn down by gentle traction to the vaginal outlet, and steadied by an assistant; the line of vaginal junction is then established, in order to avoid opening into the bladder in front or the peritoneal cavity behind; an excavation in the shape of a cone is then made in the cervix by cutting with curved scissors toward the center. As each blood-vessel is divided, the neighboring tissues should be seized with forceps as a fresh point of traction, and in this way arresting the hemorrhage. The dissection is continued until healthy tissue is reached. The vaginal tissue is then drawn over the stumps, and stitched to the lining membrane of the uterine canal with silver wire sutures. The two essential features of the operation are to secure primary union and to guard against closure of the cervical canal. To ensure the former, as many precautions against sepsis should be taken as for a laparotomy.

DISCUSSION.

DR. PAUL F. MUNDE considered the operation proposed a good one. He has often amputated elongated cervices with the knife, and stitched the mucous membrane of the vagina to the lining of the cervical canal. He generally combines the operation with anterior and posterior colporrhaphy and Alexander's operation in those cases where there is hypertrophy and prolapse of the uterus.

DR. J. RIDDLE GOFFE said he was opposed to the term "amputation of the cervix," because it gives a false impression of the procedure. He was of the opinion that all cases of laceration of the cervix can be repaired and a good result obtained by the original Emmet operation. A tightly rolled piece of gauze introduced into the canal will keep the latter patulous. In cases where one lip is degenerated or elongated and the other healthy, the former can be removed, but the equilibrium of the organ is destroyed if much of the cervix is taken away.

DR. A. PALMER DUDLEY said he understood the author to say the operation referred to was not intended to take the place of any operation which could save the cervix. He had seen cases in which the elongated cervix protruded through the vulva, and in which no operation but amputation was applicable.

DR. EMMET closed the discussion by saying that the Schroeder operation was really the Emmet operation, which the speaker had performed as far back as 1866. It was conceived by Dr. Sims, but was not successfully practised by him, on account of constant oozing of blood under the flaps and an occasional abscess.

DR. A. LAPTHORN SMITH of Montreal read a paper, entitled

RESULT OF TWO HUNDRED OPERATIONS FOR THE CURE OF RETRODISPLACEMENTS OF THE UTERUS.

Ventral fixation, the author said, is not indicated in cases where there is simply a falling back of the uterus, tubes, and ovaries, and is considered unjustifiable by most operators if the condition can be cured by other measures. Obstruction of the bowel, due to the latter being caught between the sutures, is the chief danger, and another disadvantage is the possibility of subsequent hernia.

Alexander's operation, which is without the disadvantages of the abdominal operation, and in which there is no primary mortality, is indicated in every case where the uterus is not adherent, and in many instances failures are due to inability on the part of the operator to recognize adhesions. When the uterus immediately springs back after having been brought up to the symphysis pubis, this should be considered as contraindicating the operation, and ventral fixation, or, preferably, suspension of the uterus should be performed. If the proper technic is employed, Alexander's operation can be performed in a minute or a minute and a half. A small incision should be made. The secret of success lies in cutting down to the pubis.

DR. M. D. MANN of Buffalo read a paper, entitled

INTRA-ABDOMINAL SHORTENING OF THE ROUND LIGAMENTS FOR POSTERIOR DISPLACEMENTS OF THE UTERUS.

The author described a method of shortening the round ligaments through an abdominal incision, which consisted in doubling them upon themselves in three equal lengths and stitching them together. He reported fifty-eight cases treated by this method.

DR. EDWARD REYNOLDS of Boston read a paper, entitled

A PRELIMINARY REPORT ON A NEW METHOD OF VAGINAL FIXATION.

The author described the forces, the utero-sacral ligaments behind and that attached to the anterior vaginal wall, which determine the normal position of the uterus, and showed by diagrams how a too low anterior attachment will throw the uterus backward. He advised the following procedure to overcome this condition: A short, anterior vaginal incision is made, and the bladder separated up to the level of the internal os, as previously ascertained by the sound; the uterus is now replaced, and the point at which the bladder separates from the anterior wall is carefully determined by a sound introduced into the bladder. A cervix needle, threaded with a silk carrier, is introduced in the vaginal wall at a point in front of the separation between it and the bladder, and is carried obliquely through the tissues, emerging on the cut surface just below its junction with the bladder. A silver suture is threaded on the carrier, and drawn through the cervix at the level of the internal os, and brought out through the anterior vaginal wall at a similar point upon the opposite side. A second suture is placed as near the first as possible, care being taken that the uterus is still well forward, and the sutures twisted and turned down. Coarse wire should be used, as the stitches will be exposed to considerable tension. The cut edges of the mucous membrane are then stitched together with fine catgut. It is important that the apposition of the superficial wound should not be allowed to increase the tension upon the deep sutures.

Dr. J. **Riddle Goffe** of New York read a paper, entitled

SHORTENING THE ROUND LIGAMENTS THROUGH THE ANTERIOR VAGINAL FORNIX FOR POSTERIOR DISPLACEMENTS OF THE UTERUS.

The technic of the operation was described as follows: The uterus is drawn well down to the vulva; a cross section is made at the utero-vaginal junction, and the vaginal tissues dissected off the bladder down to the peritoneal reflection; the central point of this incision is then caught up and the anterior vaginal wall drawn taut; a longitudinal incision is then made extending to the neck of the bladder, and blunt dissection from the urethra to the cross section separates the tissues for an inch and a half on either side. The peritoneum is broken through, and the finger is hooked over the fundus of the uterus which is delivered into the vagina. A free incision will permit the breaking up of all adhesions and inspection of the appendages, which may be removed, if necessary. The round ligament on one side is then caught up with the fingers, the sheath opened with an aneurism needle, the ligament drawn up two or two and a half inches, doubled upon itself, and stitched with two or three fine sutures, and the same done on the opposite side; the uterus is then replaced, and a little gauze is introduced between it and the bladder. The longitudinal incision in the vagina is closed with a running catgut suture. The author has employed this method in eight cases with entirely satisfactory results.

DISCUSSION.

Dr. **Paul F. Munde** said that inasmuch as he was the first to perform Alexander's operation in this country, he was much gratified to see how generally it has been accepted. Dr. Smith's admirable description of the first part of the technic is identical with the one the speaker has always employed. The operation results in a permanent cure in nearly all cases, and is *the* operation in cases of *movable* retroflexed uteri where the appendages are not diseased.

Dr. **Beverly McMonagle** said that Alexander's operation is often followed by suppuration and scars, and he prefers treating these cases by opening the abdomen and suspending the uterus, after the method of Kelly. He is opposed to fixation of the uterus, whether from above or below, because it interferes with pregnancy. He also referred to the pain and numbness complained of by patients who had been subjected to vaginal fixation.

Dr. A. **Palmer Dudley** said he had discarded ventral fixation because he had lost a patient from obstruction of the bowels following this operation. He never performs Alexander's operation unless he can make a diagnosis of perfect appendages.

Dr. H. J. **Garrigues** had performed Alexander's operation, combined with colporrhaphy, with good results. He did not think it is of much service if there is much descent of the uterus and hypertrophy of the supravaginal portion of the uterus. Amputation of the cervix should be performed in these cases in order to secure the involution of the uterus which follows this operation.

Dr. E. E. **Montgomery** of Philadelphia read a paper, entitled

PELVIC BLOOD COLLECTIONS AND THEIR TREATMENT BY VAGINAL INCISION.

The most common cause of internal hemorrhage and the formation of blood collections is the rupture of an ectopic pregnancy, but may be due to many other causes. Intraperitoneal hemorrhage is the most serious, and, if extensive, may be followed by such profound shock that death occurs in a few hours. In other cases the bleeding is slow and may remain encysted, become absorbed, or is discharged into the rectum, vagina, or bladder. If there is reason to believe that the hemorrhage had ceased, it is not necessary to operate on a recent case, and in this was run the risk of dislodging a clot and causing a fresh hemorrhage. In all other cases, the collection of blood should be evacuated whether it be free in the abdominal cavity or encysted. A free vaginal incision was advocated for this purpose as being the easiest method of reaching the hematocele. After clearing out the cavity, it should be irrigated with normal salt solution and packed with sterile gauze.

DISCUSSION.

Dr. **Harris** cited two cases of hematocele which had come under his observation. The first resulted from torsion of the pedicle of an ovarian tumor. The second case was that of a woman who had been confined two weeks previously, whom he had been called to see on account of an abscess of the vagina which had discharged spontaneously a few days before. A boggy tumor of the vagina was incised and a large quantity of pure blood evacuated. The cause of the hematocele could not be ascertained. Labor had been normal.

Dr. E. W. **Cushing** of Boston then read a paper, entitled

SOCIOLOGICAL ASPECTS OF GONORRHEA.

After the discussion of this paper the president introduced the newly elected president, Dr. Paul F. Mundé of New York, with a few well chosen remarks.

DR. MUNDE thanked the members for their confidence in him and said he would do all in his power to make the next meeting of the Society as successful as the present one and those which preceded it.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Held at Washington, D.C., May 4, 5, and 6, 1897.

FIRST DAY—MAY 4TH.

DR. CHARLES H. KNIGHT of New York delivered the President's Address. After a greeting to the members he called attention to the necessity of greater attention to antisepsis in clinical work. The matter had been forcibly brought to his attention by the recent observation of several unfortunate cases due to a lack of care in this respect. Closely allied to this topic is that of antisepsis in general. It may be impossible to attain perfect asepsis in nasal surgery, and in view of the perfect drainage usually attained, perhaps it is not necessary.

A question much discussed at the present time is that of the value of the laryngoscope in relation to the singing voice. In spite of the various claims made for it, it has hardly done more than to corroborate information already obtained in other ways. As to voice-production, we know from the remarkable results which have followed certain laryngectomies that intelligible speech is possible without a larynx by means of the aid afforded by the lips, tongue, palate, teeth, wall of the pharynx, nasal chambers, and the bones of the skull.

On the other hand, the mirror enables us to make out whether, in a given case of vocal impairment, the difficulty lies in faulty innervation, altered muscular action, neoplasms, hypertrophies, or simple inflammation. We are often compelled to take charge of patients who are aspirants for musical honors, but to whom Nature has denied the essentials of success; yet we may frequently assist in the restoration of a lost voice or give such advice as will lead to its recovery.

The remarkable discovery of Röntgen bids fair to be of service in the special field of laryngology. A corresponding fellow of this association, Dr. John MacIntyre of Glasgow, has successfully experimented with the rays. They will doubtless be of use in locating foreign bodies, determining the size of tumors, and in marking out the extent of malignant infiltration.

GUAIACOL AS A LOCAL ANESTHETIC IN MINOR NOSE AND THROAT OPERATIONS

was the title of a paper by DR. JAMES E. NEWCOMB of New York.

The writer said that while cocain is in a general way an ideal local anesthetic, unpleasant, not to say dangerous, effects sometimes follow its use, and attempts had been made to find a substitute for it. Eucain and tropococain had been used, and were still on trial. Quite recently guaiacol had been suggested for this purpose. Laurens of Paris had used a solution in olive oil, and reported quite promising results. In the ear, a few drops of the warmed preparation had, after preliminary cleansing, been instilled, and in fifteen or twenty minutes removed with hydrophile gauze. Sufficient anesthesia was thereby induced to enable paracentesis of the drum membrane to be painlessly performed. A similar application may be of service in incising furuncles of the meatus. In the nose, after spraying and tamponing in the usual manner, the inferior turbinates may be cauterized without any discomfort. So also polypi may be removed with the cold snare, and even with the hot wire, and septal spurs can be sawed off easily. The tissues do not retract, as with cocain, so that guaiacol can never be as serviceable as the latter where we wish to carefully inspect the nose, or in a case of supposed reflex neurosis, to determine the existence of sensitive areas.

In the pharynx, the application of the guaiacol solution may cause severe reflex movements, but sufficient anesthesia is induced to permit of cauterizing voluminous granulations and enlarged tonsils. In the larynx the incomplete absorption of the remedy proves an obstacle to satisfactory anesthesia.

These experiments of Laurens have been repeated by Geronzi, who dissolved the guaiacol in alcohol. This makes a solution a little more agreeable to handle, without apparently modifying in any way its anesthetizing power. Geronzi's results closely correspond to those of Laurens. In aural practice, he was able, under guaiacol anesthesia, to perform four myringotomies, remove granulations from the drum twice, polypi five times, and the malleus three times. In attacks of middle ear trouble, a certain disadvantage arose from the fact that the field of operation becomes obscured when the guaiacol comes in contact with the blood, probably owing to an oxidation. Geronzi suggests that guaiacol prepared by synthetic crystallization would be more constant in action and less irritating.

Dr. Newcomb had used guaiacol as a local anesthetic thirty-six times on twenty-eight different patients, sixteen men and twelve women, aged from sixteen to fifty-five years. It was used in spray, by application on tampons and hypodermically. In no instance had he noticed the formation of any emulsion or magma from admixture with the mucus. The operations included removals of polypi with the cold snare, curetting diseased ethmoid cells, the nasopharyngeal vault, and the pharyngeal wall, sawing off spurs of the nasal septum, cauterizing inferior turbinates and tonsils, and one application to the larynx preliminary to rubbing in a strong solution of lactic acid.

Anesthesia was perfect in fourteen, partial in sixteen, slight in two and entirely wanting in four cases.

DR. S. W. LANGMAID of Boston then read a paper on

SUB-MUCOUS HEMORRHAGE OF THE VOCAL CORDS.

Five cases were reported, in all of which the hemorrhage occurred at the junction of the anterior with the middle third of the cord. Four were on the right cord and one on the left. Three of the patients were men, one a woman. All were voice users, four being vocalists, the fifth an actor.

Four of the hemorrhagic patches were distinctly globular in shape and under the mucosa. The remaining one was diffuse. All came on suddenly and were the result of excessive vocal effort. A preexisting laryngeal catarrh occurred in each instance. The symptoms in all were sudden hoarseness, vocal impairment and limitation of range in the higher voice register.

The condition is, in reality, a vocal apoplexy. The preexisting catarrh lowers the laryngeal phonatory muscles; greater power than usual is, therefore, necessary to bring them into proper position. Hence, congestion, followed by vascular rupture. This accident may occur in first-class artists with irreproachable vocal technic as well as in those who are victims of faulty vocal methods.

Treatment.—Absolute rest, followed by strychnin and intralaryngeal galvanization. In none of Dr. Langmaid's cases had there been any hemoptysis. Dr. Dundas Grant had reported one case due to sneezing in which a fluid tumor (hematoma) had been the sequel of the blood extravasation.

DISCUSSION.

DR. J. W. GLEITSMANN of New York had seen one case result from a severe blow on the larynx. The late Dr. Morgan, of the Association, had reported one case of extravasation into the ventricular band.

DR. C. E. BEAN of St. Paul had seen one case in which the hemorrhage had recurred two or three times, and it was a long time before the blood was entirely absorbed.

The next paper was by DR. A. COOLIDGE, JR., of Boston on

HYSTERICAL DYSPHAGIA.

He said that this condition was frequently confounded with esophagismus or esophageal spasm, but is in reality quite distinct from it. The spasmodic condition may result from affections of the brain or tenth pair of nerves, from various reflexes from other organs, from drugs, sea-sickness, and hydrophobia.

Hysterical dysphagia is more common in women, but occasionally seen in children. Emotional causes may bring it on, and it may occur in pregnancy without assignable cause.

Symptoms are pain, sense of constriction, and feeling as of a foreign body. Onset generally sudden. A temporary lodgment of a foreign body may provoke it, the condition persisting after removal of the cause, and occasionally it is caused by affections of the pharynx and tonsils. Regurgitation is not, as a rule, observed. The sound may or may not pass readily. The trouble is observed in the first part of the act of swallowing.

Treatment should include removal of neighboring lesions and frequent passage of the bougie, but a sedulous avoidence of the esophageal electrode, as serious results have been reported from the effect on the heart through the vagus.

Discussion was opened by DR. THOMAS HUBBARD of Toledo, who spoke of sacculated dilatation of the gullet as one cause of obstruction.

DR. JOHN H. LOURNAN of Cleveland had cured one case occurring in a child of four years, with gradual onset of symptoms, by means of suggestion. Sounds should not be passed recklessly, as at least three deaths had resulted from the use of the ordinary stomach tube.

DR. GLEITSMANN had found the removal of an enlarged lingual tonsil to be efficacious in curing one case.

DR. A. L. SWAIN of New York had been led to attach much importance to enlarged lingual tonsil as a causative factor in such cases. In his own experience lingual varix had not so acted, but the fact had been insisted upon by others that it frequently did.

DR. SAMUEL JOHNSTON of Baltimore had cured one case by removal of wax from the external ear.

DR. EMIL MAYER of New York had seen one case of dysphagia in a child referable to congenital stenosis. He attached much importance to auscultation as a means of diagnosis.

DR. D. BRYSON DELAVAN of New York would always refer the etiology in the so-called hysterical cases to some definite local or neighboring lesion.

DR. JOHN A, FARLOW had seen one case in a man who, while swallowing, or in reading aloud, would have a sudden spasmodic seizure of the neck muscles. In this case the removal of impacted wax relieved all the difficulty.

DR. LANGMAID referred to the condition as observed in anemic servant girls without apparent nervousness or observable structural lesions.

DR. COOLIDGE, in closing the discussion, declared his belief that in the anemic cases the anemia was the result rather than the cause of the difficulty in swallowing.

The next paper was a joint contribution by DRS. W. H. PARK of New York and JONATHAN WRIGHT of Brooklyn

ON BACTERIA OF THE NORMAL NOSE AND BACTERICIDAL PROPERTIES OF NASAL MUCUS,

and was read by DR. WRIGHT.

The reader had, ten years ago, found pathogenic bacteria in normal noses, and his experiments had been confirmed by Von Besser. Wurts and Lermoyez had asserted that nasal mucus would destroy anthrax bacilli. Thompson and Hewlett had maintained that while bacteria were common enough in the nasal vestibule they were wanting in the deeper nasal areas.

Drs. Park and Wright examined the mucus from thirty-six normal noses. It was removed from the deeper regions on sterile cotton swabs, the vibrissæ having been cut off by sterilized blades and the vestibule washed with bichlorid. Inoculation from the swabs of culture media gave bacterial growth in all but six cases out of the entire series.

Bacteria were found on the mucosa from the noses of two healthy rabbits. In one instance the mucus withdrawn did not check the growth of diphtheria bacilli, staphylococci, or streptococci, but it did check the growth of anthrax germs. The same inhibitory result followed the employment of sterilized sheep's serum.

The comparative freedom of the interior of the nose from bacteria might be due to the washing down of the serous exudation from the higher regions which tidal air did not penetrate, the action of the ciliæ, the fact that nasal mucus is a poor culture medium for most germs, the straining action of the vibrissæ, and the fact that the ordinary bulk of inspired air contains but few germs anyway.

In the case of two rabbits, in each of whose noses one drop of a virulent bacterial culture had been allowed to fall, both died of septic infection inside of three days.

The closing paper of the session was by DR. J. W. GLEITSMANN of New York on

TREATMENT OF CHRONIC AFFECTIONS OF THE TONSILS, WITH DEMONSTRATION OF INSTRUMENTS.

Next to hypertrophy of the organ, as a whole, its most frequent chronic affection is probably the chronic inflammation of its follicles. The surface of the tonsil becomes roughened and irregular, while there is a destruction of its follicles and a plugging up of the lacunæ with white masses, which are products of inflammation. The retention of these is often the source of many ailments, whose true cause is often overlooked, as the masses are not always visible. For the proper treatment, preference is given to a small palate-hook (exhibited), by which the upper part of the tonsil where the masses most abound is easily exposed.

When the crypts contain leptothrix masses, the blunt hook of Moritz Schmidt is an excellent instrument. Dr. Gleitsmann has modified it, retaining the blunt tip, but sharpening the sides. This hook is also useful for separating adherent faucial pillars.

An inspection of the posterior surface of the tonsil is often prevented by the presence of a flap or fold of varying extent, which may seem on superficial inspection to be a part of the anterior pillar, but when the latter is drawn aside, a small deposit of lymphoid tissue is seen between the two. The greater part of the tonsil will be found behind this fold. This condition is probably the result of a previous attack of acute inflammation combined with chronic follicular disease. Harrison Allen has fully described this condition.

The proper method of removing this fold depends somewhat on its size and density. The Ruault punch-forceps are often of service. The forceps are, however, unduly large and have a vertical action, so that it is difficult to grasp the fold between the cutting-blades.

The reader of the paper then exhibited a modification of the Ruault instrument which he had devised. Its cutting direction was horizontal instead of vertical, and it was much smaller. In this class of operations it is often advisable to use cocain. If the fold is very large, several sittings may be necessary to effect complete removal. Bleeding is not severe and can be easily controlled by cracked ice, mild styptic or caustic solutions.

SECOND DAY—MAY 5TH.

A Case of Intranasal Tumor.—The patient was shown by DR. J. H. BRYAN, of Washington. He was a young man who had had nasal stenosis for about four years, due to a tumor first appearing in the left anterior and later in the right posterior naris. The septum was intact posteriorily; consequently it was inferred that the new growth had pierced the middle of the septum. From a bit removed for microscopic examination, it was found that the tumor was a fibrosarcoma, though mere inspection had suggested simple fibroma. Quite recently, diplopia and vertigo had been superadded. The growth bled freely when manipulated but there was no spontaneous hemorrhage. The most important question was as to the advisable method of removal, and the opinion of those present was solicited upon this point.

DR. M. R. WARD of Pittsburg had operated upon a case of fibrosarcoma four years ago, and though rapid recurrence had been looked for, his patient was alive to-day with no reappearances. He was inclined to think that this fortunate issue threw some doubt on the correctness of the original diagnosis.

DR. W. E. CASSELBERRY of Chicago had reported, some eight years ago, a case of simple fibroma of the nose. It could not be removed in its entirety, so he had segmented it with the galvano-cautery knife, and then removed it in pieces with the snare.

DR. JONATHAN WRIGHT of Brooklyn would regard Dr. Bryan's case as one of fibrosarcoma from the fact that the nasopharynx was not involved. Pure fibroma of the nasopharynx is common enough, but as confined to the middle and anterior part of the nose it is practically unknown.

DR. J. SOLIS COHEN of Philadelphia would advise in the present case the performance of Rouge's operation.

DR. THOMAS HUBBARD of Toledo thought that the vertigo and the diplopia suggested brain involvement, and doubted whether the case should be operated upon at all.

DR. C. C. RICE of New York would strongly advise against trying to remove such growths with the snare. It was a futile method so far as thorough eradication was concerned.

DR. J. N. MACKENZIE of Baltimore observed that the Rouge operation frequently failed to afford a complete access to the site of attachment. He would, therefore, advocate the modified Langenbeck procedure, whereby the superior maxilla was rotated outward. By this measure total eradication could be done.

DR. BRYAN then read a paper on

A CASE OF SUPPURATION OF THE FRONTAL AND MAXILLARY SINUSES.

He began by saying that recent influenza epidemics had brought to light many cases of this nature. Some cases of frontal sinus disease are undoubtedly due to propagation of disease from the antrum of Highmore, owing to an abnormal communication between the two cavities. On the other hand, the converse is more often true. The infundibulum frequently projects beyond its usual point of termination as a half tube, ending in a valve-like fold of membrane which directed the drainage from the frontal sinus into the antrum.

He then described the anatomy of the frontal sinus, showing illustrative photographs of frozen skull sections.

THE PHYSIOLOGY OF INTERNAL SECRETIONS.[1]

BY W. H. HOWELL, M.D.,
OF BALTIMORE;
PROFESSOR OF PHYSIOLOGY IN THE JOHNS HOPKINS UNIVERSITY.

SO FAR as I am aware, there is no authorized definition of the term "internal secretion," but if we adhere closely to the facts in the case, the expression may be interpreted to mean certain products that are elaborated by gland cells from material furnished by the blood, which are afterward passed back to the blood or lymph stream, to subserve some function in general or special nutrition. From the standpoint of the mechanism of secretion, a useful distinction has been drawn between these internal secretions and secretions of the usual kind, or external secretions. The latter are in all typical cases poured out upon a free epithelial surface that communicates with the exterior, while the internal secretions are discharged upon the closed endothelial surfaces of the blood and lymph vessels.

It is my purpose to-day to call your attention briefly to some of the important results obtained by experimental physiology which tend to prove the existence of internal secretions in a number of glandular organs. The main interest to the physiologist lies, perhaps, in the light this work has thrown upon the functions of the blood glands, or ductless glands, especially the thyroid, suprarenals, hypophysis cerebri, thymus, and spleen. Forty years ago the physiology of these bodies was not only unknown, but was beyond the reach of intelligent hypotheses. Within recent years facts have accumulated, especially with regard to the thyroid and suprarenals, that give us a new standpoint from which to view their physiology—a standpoint also from which experimental investigations may be planned with reasonable hope of abundant success in the future. I shall not attempt an historical review of recent work in this subject, as this has been given already in numerous general addresses and special papers.[2] I desire only to emphasize what seems to be the outcome of the physiologic work that has been done in the last twelve or thirteen years, and to explain briefly the character of the work now in progress.

If we include under the term "thyroid tissue" not only the thyroid body itself, but also the accessory thyroids and the neighboring parathyroids, it has been shown beyond reasonable doubt that complete removal of this tissue in man and the related mammals is followed, as a rule, by serious disturbances of nutrition which are immediately or ultimately fatal to the animal. Moreover, in these cases the reintroduction of thyroid material into the body, whether this introduction be made by grafting the tissue, by subcutaneous or intravascular injections, or by absorption from the alimentary canal, results in an amelioration, or even entire removal, of the symptoms of malnutrition. The physiologists recall with pleasure that these two fundamental facts were first discovered as the result of experimental work in physiology.

It follows as a logical conclusion from the successful effects attending its therapeutic use, as well as from the evil effects of its destruction or removal, that the thryoid tissue produces, normally, something that is in some way essential to the nutrition of the body. What that something is, has been revealed apparently by the beautiful chemical and clinical researches of Baumann and Roos. Baumann[1] has succeeded in isolating a substance—thyro-iodin, or iodothyrin, as it has been named more recently—which, according to the experiments of Roos,[2] preserves the beneficial effects of thyroid tissue. The fact that extracts of thyroid tissue or iodothyrin when absorbed into the blood ameliorate or remove the evil effects resulting from loss of function of the thyroid seems to prove at once that the normal function of the thyroid tissues is not merely to excrete poisonous material from the blood after the manner of the kidneys. It indicates, on the contrary, that these tissues act normally by giving off a material to the blood that in some way affects favorably the nutrition of all, or a part, of the tissues of the body. In other words, the thyroid tissues form a true internal secretion.

The most important of the facts which remain to be discovered is the manner of action of this secretion upon the tissues of the body. At present we can only speculate upon the answer to this problem. More experimental work is required before a definite solution can be reached. To account for the action of the thyroid secretion, two main hypotheses have been proposed. According to one hypothesis, the function of the secretion is antitoxic. In some way it antagonizes an unknown toxic substance supposed to be formed in the body in the course of normal metabolism. When the thyroid tissues are removed, this poisonous material, being imperfectly excreted, accumulates in the blood and produces the fatal symptoms of thyroidectomy by a process of auto-intoxication. The other hypothesis assumes that the secretion of the thyroid acts normally by promoting or regulating the metabolism of other parts of the body, particularly, perhaps, of the nervous tissues. We might designate this as the trophic or neurotrophic hypothesis. It is less specific than the antitoxic hypothesis, and therefore, perhaps, less objectionable in the present incomplete stage of our knowledge; but as no decisive, or even probable, proof can be given for either view, it seems unnecessary to critise the various facts brought forward in support of one or the other of them.

A very interesting phase of thyroid physiology which has recently come to the front is the nature of the functional relationship between parathyroid tissue and thyroid tissue proper, such as is found in the thyroid body and the accessory thyroids. The parathyroids seem to occur in all mammalia. According to a recent description by Kohn[1] there is always one of these bodies on each side attached to the external or posterior surface of the lateral lobes of the thyroid, while in some animals, *e. g.*, the dog, cat, and rabbit, there is an additional one on each side, imbedded in the substance of the thyroid lobes. Histologically, the structure of these small bodies bears no resemblance to that of the thyroid. They possess the generally appearance of embryologic tissue and have therefore been regarded usually as an immature form of thyroid tissue which, under the stimulus of increased functional activity, is capable of developing into normal thyroid structure. Satisfactory evidence is lacking that such a transformation does actually take place under the conditions supposed, as, for example, after complete excision of the two thyroid lobes. On the contrary, the evidence from histology, as well as from embryology, seems to indicate that the two tissues are not only fundamentally different in structure, but are also different in origin.

On the physiologic side, Gley[2] was the first to prove the great importance of the parathyroids. He showed that in rabbits complete extirpation of the thyroid lobes alone is not followed by fatal result, so long as the parathyroids remain. Removal of both thyroids and parathyroids, however, is in most cases followed by typical symptoms of complete thyroidectomy, ending in the death of the animal. This latter result has been contested by some observers, but renewed investigations have demonstrated its accuracy. Gley explained his results on the hypothesis that after removal of the thyroid, its function is vicariously assumed by the parathyroids. He concluded therefore that the functional value of the two tissues is identical. Recent work, however, tends to throw doubt upon this conclusion. Vassale and Generali[1] state that in dogs and cats removal of all four parathyroids produces the typical acute symptoms of complete thyroidectomy, and finally causes the death of the animal, in spite of the fact that the thyroid body proper is left practically uninjured. On the other hand, complete removal of the thyroid lobes is not immediately injurious to the animal, provided the parathyroids, or, in some cases if even one only of the parathyroids, are left. They contend, therefore, that the result in dogs and cats usually attributed to extirpation of the thyroids is due in reality to the simultaneous removal of the parathyroids.

The results of recent physiologic experiments upon the suprarenal bodies have not been less interesting, although less complete than those upon the thyroid. These curious bodies, like the thyroid, are found constantly in all classes of the vertebrates, and seem, therefore, to be organs of fundamental importance. As long ago as 1856, Brown-Séquard[2] stated that extirpation of both suprarenals is usually fatal to the animal, death occurring generally very shortly after the operation—more rapidly, according to this observer, than after removal of both kidneys. This statement has been questioned frequently by other observers, but the results of the renewed investigations that have followed the recent revival of interest in the physiology of the ductless glands seem to corroborate fully the account given by Brown-Séquard. In the case of dogs, according to Szymonowicz,[3] death follows the operation within fifteen hours. It has been shown, also, that in some species of animals accessory suprarenals are not uncommon, and it is possible that this fact may explain the survival of a certain number of animals after supposed complete extirpation of the suprarenals. Removal of only one suprarenal does not appear to cause any noticeable effect. In the case of complete removal, followed by a fatal result, the prominent symptoms preceding death are extreme muscular weakness, asthenia, and, in the case of dogs examined during this period, a great fall in blood pressure, together with a feeble heart-beat. It will be noted that in cases of Addison's disease in man the important symptoms, in addition to the pigmentation, are also an asthenic condition of the muscles and the heart. What explanation have we to offer for the surprisingly profound effect produced upon the body by the removal of these small organs?

Unquestionably the most significant facts with regard to this problem have been obtained from a study of the effects of injections of suprarenal extracts into living animals. A number of the earlier experiments of this kind, especially those performed upon rabbits, resulted in the death of the animal, the preceding symptoms being convulsive movements, followed by some paralysis. The really valuable results, however, have been obtained by a more exact study of the effects of such injections upon the vascular and respiratory organs. Most of our knowledge upon these points has been derived from the researches of Oliver and Schäfer[1] and Cybulski and Szymonowicz.[2] The important facts determined by them, and since corroborated in many laboratories, are as follows: Extracts of the medulla of the suprarenal bodies injected into the veins of a living animal cause a pronounced slowing of the heart-beat and a large rise of blood pressure. If the animal is first given atropin to paralyze the inhibitory nerves to the heart, or if the vagi are previously cut, the injection causes usually a marked quickening, instead of a slowing of the heart-beat, and a greater, indeed often an extraordinary, rise of blood pressure. The respiratory organs are not affected so seriously, a temporary slowing and shallowing of the respiratory movements being the result usually noticed. The effect upon the heart and blood-vessels is quite temporary. Its exact duration depends somewhat upon the dose, and in part upon other less evident conditions, but, as a rule, within a very few minutes the rise in blood pressure, as well as the slowing of the heart-beat, passes off completely.

The physiologic explanation of the slowing of the heart caused by the suprarenal extracts offers no difficulties. Since this effect disappears completely upon section of the vagi, or after the injection of a few milligrams of atropin, it can only be due to a stimulating action upon the central endings of the inhibitory fibers, that is, upon the so-called cardio-inhibitory center in the medulla. According to Oliver and Schäfer, the inhibitory effect is felt mainly upon the auricles. The beats of this part of the heart become weaker and slower and may cease altogether, while the ventricular beats, although slower, are more vigorous. After the vagi have been cut, suprarenal extracts cause a quicker and, according to Oliver and Schäfer, who measured the extent of contractions directly, a stronger beat. This accelerating effect upon the heart after removal of the inhibitory fibers is not due, as we might at first suppose, to a stimulation of the central ends of the accelerator fibers, since it is still obtained after section of the cord in the neck, or after extirpation of the first thoracic ganglia. It must therefore be due to a peripheral action of the extracts upon the heart itself, either upon the muscle of the heart directly (Oliver and Schäfer), or upon the so-called motor ganglia (Szymonowicz).

The effect of the injections upon blood pressure has been explained differently by those engaged in the work. Both Oliver and Schäfer, and Cybulski and Szymonowicz believe that the enormous rise in blood pressure is due mainly to a great constriction of the arterioles. According to the latter this constriction is brought about by a stimulating action of the extracts upon the vasomotor centers in the medulla and cord, while according to Oliver and Schäfer, the action is exerted directly on the muscles of the blood-vessels. Szymonowicz admits that if the cord is cut just below the medulla, a great rise of pressure can still be obtained, but he explains this by supposing that the extract acts on the spinal centers. He asserts that if the entire cord is destroyed, a rise of pressure can no longer be obtained. The experiment that he gives to illustrate this last point is, however, far from being convincing. The protocol of the experiment shows that the act of destroying the cord in itself reduced the blood pressure to zero. Moreover, Biedl[1] reports that he has been able to get a rise in pressure from injection of the extracts after complete extirpation of the cord. The evidence therefore seems to favor the view proposed by Oliver and Schäfer, and this view is still further supported by the fact that when the volume of a limb is measured plethysmographically it often shows a distinct diminution after suprarenal injection, even though its nervous connections with the central nervous system are entirely severed.

The significance of the marked reaction exhibited by suprarenal extracts depends very largely upon the possibility of proving that the substance producing the reaction is formed normally within the gland. It is conceivable, of course, that in the dead gland

post-mortem changes might cause the formation of a substance giving this reaction, although under the normal conditions of life it might never be formed. Fortunately we have direct proof that the active substance in question is a normal product of the metabolism in the gland. Cybulski and Szymonowicz found that blood drawn from the suprarenal vein when injected into the circulation of a normal animal gives the same effect, although less in amount, as extracts of the suprarenal glands, while blood from other veins has no such action. This result has been denied by Oliver and Schäfer, apparently upon insufficient experimental grounds. Langlois,[1] on the contrary, has been able to corroborate this effect of suprarenal blood, and in the laboratory at Baltimore Dr. Dreyer has obtained clear proof of a similar action. It appears from Dr. Dreyer's experiments that the effect is not obtained in every animal, but in some cases the results are very positive, and in a matter of this kind the positive evidence is the most important. When we remember that we are dealing most probably with a material formed by the secretory activity of gland cells, and that the amount of this material may vary at different times or under different circumstances, it is not surprising that negative as well as positive results are obtained.

Since it seems certain that the substance does occur under normal conditions in the venous blood flowing from the gland, we are justified in concluding that it is a normal product of the metabolism of the medullary cells of the gland, and that it is discharged or secreted directly into the blood. It must, therefore, exert continually a stimulating effect upon the heart and blood-vessels. In corroboration of this last conclusion, we have some striking experiments recorded by Szymonowicz which show that that, after complete extirpation ot the two glands, the blood pressure becomes greatly depressed. Both Oliver and Schäfer, and Cybulski and Szymonowicz conclude that the normal function of the suprarenals consists in furnishing this stimulating substance to the blood. The former observes believe that its effect is mainly upon the muscular tissue, that it has a general tonic or augmenting action on all varieties of muscle found in the body—the striated muscle, as well as the cardiac and plain muscle tissue. Cybulski and Szymonowicz hold essentially the same general view, except that they believe that the substance acts upon the nerve centers controlling the muscular tissues, rather than on these tissues directly. It is, perhaps, impossible at present to decide as to this detail. Upon either of the views proposed we can understand at once why removal of the suprarenals brings on a condition of muscular asthenia, and why the continual activity of these organs is so essential to the body as a whole. It is significant in this connection to recall that Oliver and Schäfer found that extracts of the suprarenals in cases of Addison's disease did not contain this stimulating substance.

A third interesting member of the group of ductless glands is the hypophysis cerebri, and a few words may be said as to its supposed physiologic activity. This gland is commonly described as consisting of two parts, the anterior and the posterior lobe. The histology and the embryology of the two parts indicate that they are entirely different in origin and in structure. The anterior lobe is evidently a glandular structure. It develops originally as a saccular invagination from the buccal epithelium, and has essentially the same origin in all the vertebrates which have been examined. According to Haller[1] it is not strictly a ductless gland, since it possesses an imperfectly developed system of ducts which opens between the dura and the pia mater. It is evidently a secreting structure, and the fact that its secretion is discharged between the meningeal membranes, suggests some special connection with the physiology of the brain. Histologically, its structure recalls that of the thyroid gland, particularly in the fact that a colloidal material is said to occur frequently in the lumina of the gland tubules. In some animal, *e.g.*, the dog and the cat, it is a very small body, but in others, as the rabbit, sheep, ox, and man, it is of considerable size, and bears every indication in its structure of being an active secretory organ.

The posterior lobe, on the contrary, is very small in all animals, and has the appearance of being a rudimentary organ. It develops as an outgrowth from the infundibulum of the brain, and is more properly spoken of as the infundibular lobe. Its histology is very incompletely known. According to Berkley[2] it contains numerous typical nerve-cells, ependymal cells and neuroglia, a number of glandular epithelial cells arranged in part to form tubes or closed vesicles that contain a colloidal material, and some curious structures resembling nerve-end organs. If this description is correct, it seems quite certain that the entire lobe does not originate from the nerve tissue of the brain.

The observations bearing upon the functions of the hypophysis have been limited to the glandular lobe. On the pathologic side it has been shown that in many, if not in most, of the cases of acromegalia, the glandular lobe exhibits pathologic changes.

---

[1] Langlois, *Archives de Physiologie Normale et Pathologique*, 152, 1897.

[1] *Morphologisches Jahrbuch*, xxv, 1896.

[2] Berkley, *Johns Hopkins Hospital Report*, iv, 1895.

For this reason, extracts of the gland have been used therapeutically in cases of acromegalia and, according to some reports, benefits have followed the treatment to the extent that some of the disagreeable symptoms have shown amelioration. The evidence from this side, however, is not satisfactory, and the nature of the connection between acromegalia and disturbance of the function of the hypophysis, if any exists, needs more complete investigation.

The experiments make by the physiologists are also meager and inconclusive. Gley[1] reports a set of experiments made upon rabbits in which he attempted to destroy the gland by an operation from above. The experiments were made upon rabbits from which the thyroid lobes had been previously removed, with the idea of demonstrating that a similarity in function exists between the thyroid and the hypophysis. All but one of the animals died owing to the severity of the operation. In the single survivor it was noted that the animal exhibited at times spasmodic muscular contractions, and some degree of paresis, and that it died about a year after the operation. On the assumption that the animal would have lived if the thyroid lobes alone had been removed Gley concluded that the removal of the hypophysis had prevented the parathyroids from replacing completely the loss of the thyroid, and that, therefore, the hypophysis is related in function to the thyroid tissue. Naturally but little importance can be attached to a single experiment of this kind, and so far as I know the author has not repeated the investigation. Vassale and Sacchi[2] claim to have removed the hypophysis partially or completely in a number of animals by an operation through the base of the skull. In cases of complete removal the animals died within a short time —fourteen days—after exhibiting a number of symptoms similar to those caused by thyroidectomy, such as muscular tremors and spasms, and the development of a cachectic condition. Most physiologists, I fancy, will accept these experiments also with considerable hesitation. The very severe character of the operation necessary to reach the gland makes it questionable whether the results reported were due to its removal alone.

Szymonowicz, and also Oliver and Schäfer, report experiments upon the effects of injections of extracts of hypophysis into the circulation of normal animals. Szymonowicz states that in two experiments he obtained a slight fall of pressure and a quickening of the heart-beat. He concludes, therefore, that the physiologic action of these extracts is opposed to that caused by extracts of the suprarenals. Oliver and Schäfer, on the contrary, report that extracts of hypophysis exert an effect very similar in some ways to that shown by suprarenal extracts. For instance, they cause a marked rise of blood pressure, together with an augmentation of the heart-beat. Unlike the suprarenal extracts, however, they do not produce a slowing of the heart-rate when the vagi are intact. Upon the basis of these incomplete experiments, they draw the hasty conclusion that the hypophysis and the thyroid are not similar in function, and that the hypophysis is not capable of assuming vicariously the the activities of the thyroid.

I have recently made a number of experiments upon this organ, the results of which have been quite uniform, and in many respects very different from those obtained by the authors just quoted. My experiments were made with the hypophysis of sheep mainly, although at first the gland of the dog was used. The extracts were made in normal saline, or in glycerin followed by dilution with normal saline, and usually the fresh gland was employed. The experiments differed from those reported by others, in that extracts were made separately of the glandular and the infundibular lobe, and the physiologic effects of each were tested by injection into the circulation of normal dogs. It was found that the extracts of the glandular lobe have little or no perceptible effect when injected alone. Extracts of the small infundibular lobe, on the contrary, have a distinct and remarkable effect upon the heart-rate and blood pressure, an effect which resembles in some respects, and differs in others, from that shown by suprarenal extracts. Briefly stated, these extracts injected into the normal animal with its vagi intact cause a very pronounced slowing of the heart-beat, similar to that caused by suprarenal extracts, but lasting a much longer time. The heart-beat is not only slowed but is considerably augmented in force, as is shown by tracings taken with a Hürthle manometer. At the same time the blood pressure rises to a considerable extent, owing, apparently, to a peripheral constriction of the blood-vessels, since oncometer tracings from the kidney show that this organ shrinks greatly in volume. Usually the constriction of the blood-vessels occurs first, so that the pressure rises for about twenty millimeters or more of mercury. This is succeeded sometimes by a temporary fall of pressure during which the heart-rate may be increased, and then the slowing of the heart begins, while the pressure rises again to a greater or less extent above the normal. This last effect continues for a relatively long time, and passes off gradually. If the dose used is a maximal one, and a second injection is given too quickly afterward, little or no effect is obtained. If, however, the dose is not too strong, and sufficient time is given for its action to wear off, a repetition of the effects is obtained, and this may occur a number of times, although the effects decrease progressively in intensity.

---

[1] Gley, *Archives de Physiologie Normale et Pathologique*, 1892, 311.

[2] Vassale and Sacchi, *Archives Ital. de Biologie*, xxi, cxxxiii, 1895.

The effects of the injection are somewhat different if the vagi are previously cut, or if a little atropin is given to paralyze the inhibitory fibers. Under these circumstances the slowing of the heart-rate is very much less marked, although not entirely lacking. In round numbers it may be said that, with the vagi intact, the heart-rate is reduced about fifty per cent., while in the atropinized animal the reduction is about twenty per cent. It might be added that an animal deeply under ether behaves in this respect like an animal with its vagi cut. This result indicates that the slowing of the heart-rate in a normal animal is due in part, but only in part, to a direct action on the medullary centers of the inhibitory fibers. On the other hand, the rise of blood pressure is greater. Usually the blood pressure rises rapidly for about twenty millimeters of mercury; this is succeeded in some cases by a temporary fall, and then the pressure again rises rapidly, reaching a height, in some cases, nearly equal to that caused by suprarenal extracts. During this last phase the heart-beats are somewhat slower and more powerful, the effect in this respect differing from that caused by suprarenal extracts. The effect lasts longer than with suprarenal extracts, and a longer interval must be allowed before a new injection will give the same result.

I have obtained a marked rise of pressure from injection of extracts of the infundibular lobe, after severance of the cord below the medulla, and in one case after entire removal of the thoracic part of the spinal cord in addition, thus indicating that the action of the blood-vessels is probably a peripheral effect, and not due to stimulation of the vasomotor centers. These observations that I present here only incompletely may be taken to indicate that the infundibular lobe of the hypophysis is, in all probability, not a rudimentary organ, but a structure that has some important physiologic activity. Moreover, its function is probably different from that of the grandular lobe, and possibly quite independent of it. With regard to the function of the glandular lobe, the method of injecting extracts into the circulation of a normal animal seems to teach us nothing. While the negative results thus obtained do not oppose, they cannot be said to support the favorite hypothesis that this part of the hypophysis cerebri has a function resembling that of the thyroid lobes. I venture to suggest that this supposed similarity in function might be tested most satisfactorily upon human beings by feeding the gland in cases of myxedema or goiter, and ascertaining whether a reaction similar to that caused by the thyroid can be obtained.

A CLINICAL STUDY OF THE ACTION OF THE NUCLEINS IN TUBERCULOSIS.

By HERBERT MAXON KING, M.D.,
OF GRAND RAPIDS, MICH.;
PHYSICIAN TO THE BUTTERWORTH HOSPITAL; FORMERLY INSTRUCTOR IN LARYNGOLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

In passing judgment on the value of the nucleins in the treatment of tuberculosis, and before forming too hasty conclusions from the report which I submit herewith, a few important facts regarding these products, their preparation and elaboration, and the technic of their administration must be considered in order that the true value of nuclein, as a therapeutic agent, may be estimated with some degree of fairness.

It is not within the scope of this paper, nor is it at all necessary here, to enter into an exhaustive account of the early history of these products, nor to go into details of their growth and elaboration to the stage of perfection which they have reached. The work on the nucleins pursued by Hoppe-Seyler, Miescher, Von Jaksch, Kossel, Altmann, Horbaczewski, Vaughan, and McClintock, has been ably reviewed in several masterly papers by Professor Vaughan and Dr. McClintock, notably in the annual address on medicine, "The Nucleins and Nuclein-therapy," delivered in 1894 at the meeting of the Michigan State Medical Society (see "Trans. Mich. State Med. Soc.," 1894), to which all have access; but it does seem necessary in considering the subject to remember that nuclein is a comparatively new therapeutic agent, scarcely three years having elapsed since its introduction. Again, it must be remembered that when first employed therapeutically the solutions obtainable contained many impurities which were afterward eliminated to a certain extent, and that the actual chemical value of the solutions was an uncertainty. This placed its hypodermic employment at a disadvantage, and made the estimation of the clinical value a slow process. Hypodermic medication in any event, involves special attention to the behavior of the patient, and to the general supportive treatment. Idiosyncrasies demand closer observation and attention, and especially when treatment is directed, as in the case of nuclein in tuberculosis, toward altering the process of normal metabolism. Furthemore, in tuberculosis we have to deal with a disease usually of very slow development, to change the course of which is at best, and under most favorable circumstances, a matter of considerable time. With all this in view it is perfectly obvious that a fair estimate of the value of any remedy directed to the cure of tuberculosis cannot be made from the clinical history of a single case, nor from that of any number of cases in the space of a few months.

Early in August, 1894, I began the employment of solutions of yeast nuclein in the treatment of tuberculosis in man, and until the present time I have felt that any report which I might make on the subject would neither be of value to the profession, or just to the remedy. In the following report I have made no attempt at a selection of cases, and I have endeavored in every instance to take a conservative view of the results as they were obtained, and to form no conclusions not founded upon demonstrable facts. The preparations of nuclein which I have employed in the treatment of the cases reported have been as follows: The original impure solution supposed to contain 2 per cent. of nucleinic acid (afterward found to contain much less than that); the improved 1-per-cent. solution, which was first obtainable in June, 1895 (the improvement consisting, according to Dr. McClintock, essentially, in the removal of a lot of impurities, for the most part albumins, and a considerable amount of coloring matter, the nature of which is unknown, but probably having some connection with the Xanthin bases); some 3-per-cent., and 10-per-cent. solutions, prepared for me through the kindness of Dr. McClintock, and the solution now obtainable containing 5 per cent. of nucleinic acid. All these have been solutions of *yeast* nuclein, and, although I have used them per os to a very limited extent as an adjunct to the hypodermic method, it is from the hypodermic employment that I have obtained the results reported below. Besides these solutions of yeast nuclein I have used a dry, powdered spleen nuclein per os, mainly as an adjunct to the hypodermic use of the solutions. This product, according to McClintock, contains about 6 per cent. of phosphorus, and is practically a pure nucleinic acid prepared from the spleen. I was enabled to obtain this product also through the courtesy of Dr. McClintock.

As regards the dosage and the technic of administration, I used the original impure solution in daily hypodermic injections of from 30 to 100 minims given at one dose. These injections of course occasioned considerable pain and induration at the point of injection, and often had to be discontined for a short time. The reaction generally was considerable, and in two instances was so severe that the treatment was abandoned as impracticable. These two cases are included among my "failures," so termed. As soon as the improvements before mentioned were made in the preparation of the solution I increased the dosage until in a few cases I reached 300 minims, injected hypodermically once daily. This dose, however, was too large in the majority of cases, causing considerable reaction attributive to the mechanical presence of so large an amount of fluid in the tissues, and I found that the best results were obtained from injections of from 100 to 200 minims.

In the case of the 3-per-cent. solution, which was the first strong solution employed, I made the injection daily of 100 mimims, with very little unpleasant reaction. The hypodermic use of the 10-per-cent. solution was wholly an experiment, and I began with 10 minims, increasing to 50 minims, and in two instances I injected 100 minims at a single dose. This was followed in both cases by such violent reaction, however, that I afterward never exceeded 50 minims at a single injection. This concentrated solution was used in four cases, all of which improved rapidly, but the care and attention to details of technic which the employment of this preparation necessitated convinced me that for practical purposes the more dilute solutions are preferable. Finally, I speak of the 5-per-cent. solution which has now been obtainable for some time. When first given to the profession it was intended for administration per os only, but I have always employed it hypodermically and have obtained far better results from it than from any other preparation of yeast nuclein which I have used. While having given as high as 100 minims at a single dose, I have found that in tuberculosis the best results are obtained from daily injections of 50 minims. It is unnecessary to add that in nuclein medication no arbitrary rules of dosage can be laid down. Good judgment and proper attention to idiosyncrasies, together with a suitable and appropriate supportive treatment, are essential to success.

In my experience, the portion of the body best adapted to the reception of the injection is, in the great majority of cases, the subcutaneous areolar tissue overlying the gluteal muscles. In some instances, they may with impunity be administered below the angles of the scapulæ, or low down in the axilæ. In the shoulders and breasts they cause more local disturbance, while in the arms, legs, or thighs, the injections occasion far more pain and local reaction than will be borne by patients generally, and especially by those not confined to bed. In making the injection, the surface of the part selected is exposed and sponged thoroughly with a 5-per-cent. solution of carbolic acid; the needle is then inserted its full length (one inch) at an angle of about seventy-five degrees, and the piston steadily pressed until all of the solution is injected. When the dose is 50 minims, fifteen seconds should be allowed for the injection. With the observance of these simple precautions the least possible pain is inflicted, and I have never had suppuration follow, except in one case, when it was directly attributable to lack of proper care of the needle. Patients should, of course, be supplied with their own needles. I have often been asked what nature of reaction might be expected to follow nuclein injections, and to what degree it might occur without contraindicating its employment. Leaving idiosyncrasies out of consideration, I have found that in the majority of cases the local reaction is merely one of mechanical disturbance dependent for its extent upon the *amount* of the solution injected. Dr. McClintock early pointed out to me the importance of the chemical reaction of the solutions used as affecting the irritation following the injection. I have not found any marked difference in the irritation produced by injections of solutions which are slightly acid, neutral, or slightly alkaline in reaction. A slight alkalinity of the solution is undoubtedly preferable because it is possibly less irritating, and because it is more readily absorbed. The symptomatic reaction varies in different cases. An injection of unusual size or concentration is followed by a rise of temperature of from .4° to 3° F., and a proportionate pulse-rate. This reaction is much less in degree if the maximum dosage is approached gradually. Rise of temperature and increase in pulse-rate are produced by hypodermic injections of nuclein solutions in healthy persons, as may be remarked in the experiments to be reported presently. After the injections have been repeated for a considerable number of consecutive days, patients sometimes complain of a "malarial aching" in the joints, and a feeling of general malaise, passing off later with the physiological accommodation which follows. These and various other subjective symptoms which are often observed to follow nucleinic medication are, in my opinion, due to the continued leucocytosis produced by the nuclein injections when often repeated.

In the following report I shall avoid as far as possible the tedium of exhaustive detail which a clinical account of a considerable number of cases at best involves, and limit myself to general results except when special interest requires more complete individual discussion. Suffice it to say that in the 37 cases reported there has been no question as to diagnosis. In all but 3, the diagnosis was confirmed by the presence of tubercle bacilli in the sputum or urine, or both. Two of these 3 were cases of tuberculous lymphangitis without pulmonary involvement, in 1 of which the diagnosis was made a number of years before by the microscopic appearance of one of the glands after surgical removal, while in the other diagnosis was confirmed by several eminent clinicians. In the third case, in which bacilli were not found, there was no expectoration, the process in the lungs never having gone beyond consolidation. It was pronounced tuberculosis upon the evidence presented by the physical signs, together with that of the personal and family history. The average age of the 37 patients was 31.2 years, the extremes being 16 and 61 years, respectively. Eighteen cases were complicated by tuberculous disease elsewhere than in the lungs; of these, as the report will show, 10 had tuberculous laryngitis, and of the remaining 8, 5 had nephritis, 2 had lymphangitis, and 1 had tuberculosis of the testes, and of one or more of the vertebræ.

Classification of patients suffering from tuberculosis is rather an unsatisfactory, not to say difficult, matter, and the plan which I have adopted does not fully meet the requirements of a finished statistical report, but I think it the least objectionable of any which does not involve individual record, and in a paper like the present it may be well to add that in every instance I have kept a complete clinical record, the important results of which are embodied in this report. I have classified the cases reported, (1) according to the length of time treated; (2) according to the stage which the disease had reached when treatment was begun, *i.e.*, incipient, advanced, and far advanced, and (3) according to the complications existing. Proceeding, therefore, under this classification, the first to be considered is:

Class I.—(10 patients treated one month or less.) (*a*) Incipient stage, 2; advanced stage, 3; far advanced stage, 5; (*b*) uncomplicated, 5; laryngeal complications, 3; other complications, 2.

Results in Class I.—Apparently cured, 1; disease arrested, 0; improved, 0; unimproved or failure, 9; died during treatment, 0; died since cessation of treatment, 5; present condition unknown, 1; known to be living, 4.

In this class, for obvious reasons, failure is the rule. In one case this was due to arbitrary unwillingness on the part of the patient to continue the injections, while in three cases nuclein was inadmissable on account of idiosyncrasies. Two of these three, as before mentioned, were under observation and treatment prior to the improvements made in the nuclein solutions. The majority of the failures reported in this, as in other classes, were expected from the first, the treatment being adopted more to gratify the desire of the patient than with any hope of success. Yet even in these forlorn patients I have occasionally seen the most marked temporary improvement follow the injections.

It might be well here to briefly explain what is meant by "apparently cured." In tuberculosis we have a pathologic condition which, after the incipient stage, is marked by destruction of tissue. It is clearly impossible to replace any part or the whole of a broken-down lung, but when we have assisted nature to throw out protecting adhesions, and procured a clean cicatrix in the place of a suppurating surface, it seems to me only reasonable to pronounce the result a cure, in the sense that surgical amputation for a gunshot wound of the knee-joint is a cure; but at the same time, since it is impossible to pronounce a tuberculous wound cured, even after the subsidence of morbid activity, until it has *remained* well for a reasonable length of time without relapse, and since I do not consider two years a sufficiently rigid time-test in these cases, I prefer to designate such cases as have given me this happy result in this way. This number embraces such as have ceased to show all physical manifestation of morbid activity.

I proceed now to the consideration of

Class II.—(12 patients treated from one to three months.) (*a*) Incipient stage, 3; advanced stage, 4; far advanced stage, 5; (*b*) uncomplicated, 7; laryngeal complications, 3; other complications, 2.

Results in Class II.—Apparently cured, 3; disease arrested, 2; improved, 4; unimproved or failure, 3; died during treatment, 1; died after cessation of treatment, 0; present condition unknown, 3; known to be living, 8.

Class III.—(12 patients treated from three to twelve months.) (*a*) Incipient stage, 1; advanced stage, 6; far advanced stage, 5; (*b*) uncomplicated, 4; laryngeal complications, 5; other complications, 3.

Results in Class III.—Apparently cured, 3; diseased arrested, 3; improved, 2; unimproved or failure, 4; died during treatment, 2; died after cessation of treatment, 3; present condition unknown, 0; known to be living, 7.

Class IV.—(3 patients treated for more than one year.) (*a*) Incipient stage, 1; advanced stage, 2; far advanced stage, 0; (*b*) uncomplicated, 3; laryngeal complications, 0; other complications, 0.

Results in Class IV.—Apparently cured, 1; disease arrested, 2; improved, 0; unimproved or failure, 0; died during treatment, 0; died after cessation of treatment, 0; present condition unknown, 2; known to be living, 3.

GENERAL SUMMARY.

Classification.—(37 patients treated.) (*a*) Incipient stage, 7; advanced stage, 15; far advanced stage, 15; (*b*) uncomplicated, 19; laryngeal complications, 10; other complications, 8.

General Results.—Apparently cured, 8; disease arrested, 7; improved, 6; unimproved or failure, 16; died during treatment, 3; died after cessation of treatment, 8; present condition unknown, 6; known to be living, 22.

Leaving out of consideration those cases reported under "disease arrested" and "improved" we have nearly 22 per cent. of apparent cures, a result which I cannot but consider eminently satisfactory. And it is worthy of consideration, also, that this result has been obtained without recourse to change of climate, in a portion of Michigan where the disease in question is notoriously prevalent. By far the majority of these patients were members of families of *very* limited means, unable to procure any of the luxuries and deprived of many of the necessities within reach of the rich. So far as was possible hygienic conditions were improved, and, as I have intimated, strict attention was given to the general supportive treatment and nutrition.

Now as to the effect of the treatment upon the prominent symptom of the disease. As regards the expectoration: Number of patients in whom the expectoration contained bacilli of tuberculosis: Before treatment, 34; after treatment, 26. Number of patients who had either no bacilli or no expectoration: Before treatment, 3; after treatment, 11. Number of patients who gained in weight under treatment, 16; number of patients who lost in weight under treatment, 11; number of patients whose weight was not recorded, 10.

I now desire to call attention to what I consider some very important observations relative to the comparative value of the blood in tuberculous patients treated with nuclein. Unfortunately, I delayed making these investigations in several cases until the patients had already been treated for some time, so that the gain or loss in those cases does not date from the commencement of the treatment. I will report the result in 10 cases, which I think will be a sufficient number upon which to base conclusions. The observations were taken in all cases at least twenty-four hours after the last previous treatment, and as far as possible all observations in the same patient were made under like conditions, that is, as to time of day, temperature, pulse, and intervals from the taking of food. The Thoma-Zeiss counting apparatus and Von Fleischl's hemoglobinometer were used in all cases.

CASE I.—Treatment begun May 2d. Daily hypodermic injections of 100 minims of a 1-per-cent. solution of yeast nuclein, and 10 grains of nucleinic acid from the spleen *per os*, three times daily. First examination, June 15th: Red corpuscles, 4,125,000 per c.mm.; white corpuscles, 9150 per c.mm.;

hemoglobin, 65 per cent. normal. Proportion of white to red corpuscles, 1:451. Second examination, one month later: Red corpuscles, 4,550,000 per c.mm.; white corpuscles, 9650 per c.mm.; hemoglobin, 90 per cent. normal. Proportion of white to red corpuscles, 1:471. An increase in red corpuscles of 425,000 per c.mm.; an increase of hemoglobin of 25 per cent. This case was one of "apparent cure."

Case II.—Treatment began May 22d, same as in last case reported. First examination, June 15th: Red corpuscles, 3,475,000 per c.mm.; white corpuscles, 12,900 per c.mm.; hemoglobin, 60 per cent. normal. Proportion of white to red corpuscles, 1:296. Second examination, fifteen days later: Red corpuscles, 3,650,000 per c.mm.; white corpuscles, 12,800 per c.mm.; hemoglobin, 55 per cent. normal. Proportion of white to red corpuscles, 1:285. (Numerous microcytes present.) An increase in red corpuscles of 175,000 per c.mm.; a loss in hemoglobin of 5 per cent. This case is reported among the "failures."

Case III.—Treatment began May 25th, same as in previous case. First examination, June 15th: Red corpuscles, 3,550,000 per c.mm.; white corpuscles, 15,000 per c.mm.; hemoglobin, 65 per cent. normal. Proportion of white to red corpuscles, 1:237. (Numerous poikilocytes present.) Second examination, one month later: Red corpuscles, 4,325,000 per c.mm.; white corpuscles, 15,600 per c.mm.; hemoglobin, 75 per cent. normal. Proportion of white to red corpuscles, 1:271. (No poikilocytes present.) Increase in red corpuscles of 875,000 per c.mm.; an increase in hemoglobin of 10 per cent. This case is reported as "disease arrested."

Case IV.—Not previously treated. Treatment consisted in injections every alternate day of 30 to 50 minims of a 5-per-cent. nuclein solution, and administration of the dry spleen nuclein, as in the other cases. First examination: Red corpuscles, 4,175,000 per c.mm.; white corpuscles, 8200 per c.mm.; hemoglobin, 80 per cent. normal. Proportion of white to red corpuscles, 1:509. Second examination, one month later: Red corpuscles, 3,550,000 per c.mm.; white corpuscles, 34,050 per c.mm.; hemoglobin, 70 per cent. normal. Proportion of white to red corpuscles, 1:104. (Numerous microcytes present.) Loss in red corpuscles of 625,000 per c.mm.; a loss in hemoglobin of 10 per cent. This case is reported among the "failures."

Case V.—Had been under treatment for one year. Treatment same as in case last reported, except that 50 minims of a 5-per-cent. nuclein solution were injected daily. First examination: Red corpuscles, 3,900,000 per c.mm.; white corpuscles, 8125 per c.mm.; hemoglobin, 80 per cent. normal. Proportion of white to red corpuscles, 1:480. (Poikilocytes present.) Second examination, five months later: Red corpuscles, 4,425,000 per c.mm.; white corpuscles, 10,900 per c.mm.; hemoglobin, 85 per cent. normal. Proportion of white to red corpuscles, 1:406. (No poikilocytes present.) An increase in red corpuscles of 525,000 per c.mm.; an increase of hemoglobin of 5 per cent. This case is reported as "disease arrested."

Case VI.—Not previously treated. Treatment same as in last case. First examination: Red corpuscles, 4,375,000 per c.mm.; white corpuscles, 12,500 per c.mm.; hemoglobin, 85 per cent. normal. Proportion of white to red corpuscles, 1:350. Second examination, one month later: Red corpuscles, 3,350,000 per c.mm.; white corpuscles, 11,550 per c.mm.; hemoglobin, 70 per cent. normal. Proportion of white to red corpuscles, 1:290. Loss in red corpuscles of 1,025,000 per c.mm.; a loss in hemoglobin of 15 per cent. This case is reported among the "failures."

Case VII.—Not previously treated. Treatment same as in last case. First examination: Red corpuscles, 3,275,000 per c.mm.; white corpuscles, 12,150 per c.mm.; hemoglobin, 50 per cent. normal. Proportion of white to red corpuscles, 1:269. Second examination, one month later: Red corpuscles, 4,650,000 per c.mm.; white corpuscles, 8000 per c.mm.; hemoglobin, 60 per cent. normal. Proportion of white to red corpuscles, 1:581. Increase in red corpuscles of 1,375,000 per c.mm.; an increase of hemoglobin of 10 per cent. This case is reported as "improved."

Case VIII.—Treated six days. Treatment same as in last case. First examination: Red corpuscles, 4,775,000 per c.mm.; white corpuscles, 17,150 per c.mm.; hemoglobin, 80 per cent. normal. Proportion of white to red corpuscles, 1:278. Second examination, three months later: Red corpuscles, 4,950,000 per c.mm.; white corpuscles, 13,100 per c.mm.; hemoglobin, 90 per cent. normal. Proportion of white to red corpuscles, 1:378. Increase of red corpuscles of 175,000 per c.mm.; an increase of hemoglobin of 10 per cent. This case is reported as "disease arrested."

Case IX.—Not previously treated. Treatment: Daily injection of 100 minims of a 3-per-cent. nuclein solution. First examination: Red corpuscles, 3,425,000 per c.mm.; hemoglobin, 90 per cent. normal. Second examination, six months later: Red corpuscles, 4,300,000 per c.mm.; hemoglobin, 100 per cent. normal. Increase in red corpuscles of 875,000 per c.mm; an increase of hemoglobin of 10 per cent. This case reported as "apparently cured."

Case X.—Not previously treated. Treatment: Daily injections of 50 minims of a 10-per-cent. nuclein solution. First examination: Red corpuscles, 4,125,000 per c.mm.; white corpuscles, 14,050 per c.mm.; hemoglobin, 65 per cent. normal. Proportion of white to red corpuscles, 1:222. Second examination, one month later: Red corpuscles, 5,050,000 per c.mm.; white corpuscles, 8125 per c.mm.; hemoglobin, 85 per cent. normal. Proportion of white to red corpuscles, 1:621. Increase in red corpuscles of 925,000 per c.mm.; an increase in hemoglobin of 20 per cent. This case is reported as "apparently cured."

Vaughan early pointed out that the nucleins, when introduced into the circulation, produced, in some manner not satisfactorily explained, a certain degree of leucocytosis, notably an increase in the number of the polynuclear cells, and to this action has been attributed the potency of the nucleins in tuberculosis rather more than to any germicidal properties which they themselves may possess. This, to my mind, is the most logical explanation of the remedial action of the nucleins in tuberculosis. To demonstrate, with an attempt at accuracy, the degree of leucocytosis produced by the hypodermic injection of yeast nucleinic solutions in tuberculosis, I made the following experiments upon six patients suffering from the disease, controlling the results by those obtained in the cases of two perfectly healthy adults (my wife and a trained nurse who kindly offered to assist me in this work). These experiments and observations were conducted with such attention to the details of technic as would insure for me the closest approach possible to perfect accuracy in results. In every instance the figures given represent the average of 256 cubic millimeters. This, in addition to the fact that the utmost care was taken regarding the dilution of the blood and the even mixture of the same, should, I believe, give a very exact estimation of the degree of leucocytosis produced, and the proportionate changes in the relative number of the mononuclear and polynuclear cells. Particular attention was paid to the state of the digestive organs, in order to insure the same conditions at the time of both examinations. The results were as follows:

SIX EXPERIMENTS UPON PATIENTS UNDER TREATMENT FOR TUBERCULOSIS.

Experiment I.—Before the injection, temperature, 99.1° F.; pulse, 76. Total number of leucocytes per c.mm., 10,900; number of mononuclear cells per c.mm., 5900; number of polynuclear cells per c.mm., 5000. Three hours after an injection of 50 minims of 5-per-cent. solution of nucleinic acid was given, temperature, 99.2° F.; pulse, 104. Total number of leucocytes per c.mm., 15,900; number of mononuclear cells per c.mm., 5600; number of polynuclear cells per c.mm., 10,300; increase in the total number of leucocytes per c.mm, 5000; loss in the number of mononuclear cells per c.mm., 300; increase in the number of polynuclear cells per c.mm., 5300.

Experiment II.—Before the injection, temperature, 98.8° F.; pulse, 84. Total number of leucocytes per c.mm., 13,100; number of mononuclear cells per c.mm., 6250; number of polynuclear cells per c.mm., 6850. Five hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid was given, temperature, 99.6° F.; pulse, 84. Total number of leucocytes per c.mm., 18,100; number of mononuclear cells per c.mm., 5950; number of polynuclear cells per c.mm., 12,150; increase in the total number of leucocytes per c.mm., 5000; loss in the number of mononuclear cells per c.mm., 300; increase in the number of polynuclear cells per c.mm., 5300.

Experiment III.—Before injection, temperature, 99.6° F.; pulse, 104. Total number of leucocytes per c.mm., 9050; number of mononuclear cells per c.mm., 3750; number of polynuclear cells per c.mm., 5300. Five hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid was given, temperature, 101.3° F.; pulse, 104. Total number of leucocytes per c.mm., 17,800; number of mononuclear cells per c.mm., 6550; number of polynuclear cells per c.mm., 11,250; increase in the total number of leucocytes per c.mm., 8750; increase in the number of mononuclear cells per c.mm., 2800; increase in the number of polynuclear cells per c.mm., 5950.

Experiment IV.—Before injection, temperature, 98.4° F.; pulse, 68. Total number of leucocytes per c.mm., 10,300; number of mononuclear cells per c.mm., 5650; number of polynuclear cells per c.mm., 4650. Four hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid, temperature, 98.4° F.; pulse, 84. Total number of leucocytes per c.mm., 11,550; number of mononuclear cells per c.mm., 4400; number of polynuclear cells per c.mm., 7150; increase in the total number of leucocytes per c.mm., 1250; loss in the number of mononuclear cells per c.mm., 1250; increase in the number of polynuclear cells per c.mm., 2500.

Experiment V. — Before injection, temperature, 99.3° F.; pulse, 112. Total number of leucocytes per c.mm., 9050; number of mononuclear cells per c.mm., 6550; number of polynuclear cells per c.mm., 2500. Five hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid, temperature, 101° F.; pulse, 120. Total number of leucocytes per c.mm., 11,850; number of mononuclear cells per c.mm., 3100; number of polynuclear cells per c.mm., 8750; increase in the total number of leucocytes per c.mm., 2800; loss in the number of mononuclear cells per c.mm., 3450; increase in the number of polynuclear cells per c.mm., 6200.

Experiment VI.—Before injection, temperature, 102.6° F.; pulse, 120. Total number of leucocytes per c.mm., 17,150; number of mononuclear cells per c.mm., 5300; number of polynuclear cells per c.mm., 11,850. Five hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid, temperature, 101.1° F.; pulse, 112. Total number of leucocytes per c.mm., 19,050; number of mononuclear cells per c.mm., 10,000; number of polynuclear cells per c.mm., 9050; increase in the total number of leucocytes per c.mm., 1900; increase in the number of mononuclear cells per c.mm., 4700; loss in the number of polynuclear cells per c.mm., 2800.

TWO CONTROL EXPERIMENTS UPON HEALTHY ADULTS.

Experiment I. — Before injection, temperature, 98.8° F.; pulse, 80. Total number of leucocytes per c.mm., 6250; number of mononuclear cells per c.mm., 2500; number of polynuclear cells per c.mm., 3750. Five hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid, temperature, 99.3 F.; pulse, 84. Total number of leucocytes per c.mm., 33,400; number of mononuclear cells per c.mm., 12,800; number of polynuclear cells per c.mm., 20,600; increase in the total number of leucocytes per c.mm., 27,150; increase in the number of mononuclear cells per c.mm., 10,300; increase in the number of polynuclear cells per c.mm., 16,850.

Experiment II. — Before injection, temperature, 98.4° F.; pulse, 65. Total number of leucocytes per c.mm., 5300; number of mononuclear cells per c.mm., 2800; number of polynuclear cells per c.mm., 2500. Five hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid, temperature, 99.4° F.; pulse, 84. Total number of leucocytes per c.mm., 21,850; number of mononuclear cells per c.mm., 6550; number of polynuclear cells per c.mm., 15,300; increase in the total number of leucocytes per c.mm., 16,550; increase in the number of mononuclear cells per c.mm., 3750; increase in the number of polynuclear cells per c.mm., 12,800.

It will be observed that in these experiments the presence of yeast nuclein in the circulation produced leucocytosis in every instance; that in every instance, except one, the increase was markedly in favor of the polynuclear cells, which we may now regard as phagocytes; that where no morbid influences existed the phagocytosis was infinitely more marked, as was the general leucocytosis, there being (in the two control experiments) an increase in leucocytes of about 540 per cent. in the one case, and 412 per cent. in the other within five hours after an injection of 50 minims of a 5-per-cent. solution of nucleinic acid was given; and, finally, that during the exacerbations of a septic fever, when there is a pathologic leucocytosis, the effect of the nuclein is less marked, but quite in accord with the physiologic process.

I have made numerous other experiments and observations respecting the action of the nucleins in tuberculosis, some of them of considerable interest, but the limits of this article have been already reached, and my conclusions must be drawn from those which have already been reported.

My conclusions, then, are as follows: (1) Nuclein is in no sense of the word a *specific in tuberculosis* but a perfectly logical remedy which acts in unison with, and as a stimulant to, the physiologic function of animal resistance to the invasion of disease. (2) Indirectly (probably) nuclein acts as a stimulus to constructive metamorphosis, as may be seen by the increase in the number of red blood-corpuscles, and in the percentage of hemoglobin which follow its repeated injection. (3) The hypodermic employment of nuclein (excepting in the presence of idiosyncrasies) is well borne by the great majority of patients, and is not contraindicated in any stage of tuberculosis, although in those cases far advanced in the disease success, beyond allaying distressing symptoms, need not be expected. (4) The most satisfactory results in tuberculosis are to be obtained from injections of moderate size made in a single dose once daily. (5) Administration of the nuclein per os is of very doubtful benefit, and should be employed only as an adjunct to their hyperdermic use, or when circumstances preclude the possibility of the latter method being adopted. (6) Success in nuclein medication in tuberculosis in the great majority of cases can only be expected to follow a continued treatment extending over a considerable period of time. (7) The same care and attention should be bestowed upon the general supportive treatment when nuclein is used as when any other method of treatment is employed. (8) Finally, nuclein medication has given far better clinical results in tuberculosis (by actual statistics) than any other medicinal agent heretofore employed in the treatment of this disease.

In closing this report I desire again to call attention to the fact that, while nuclein has passed the stage of a medical "fad," it is still a comparatively new remedy which must be critically discussed by the profession. Those who employ it should be alert of observation, strict in their clinical records and conservative in forming conclusions. By observance of these precautions we may hope through a multitude of counsel to attain wisdom as to the true status of the nucleins in medicine.

More Dispensaries in New York Seeking Incorporation.—It is reported that the following institutions have filed applications for certificates of incorporation with the State Board of Charities: The St. Bartholomew's Clinic connected with St. Bartholomew's Episcopal Church, New York city; the hospital and dispensary of the Pasteur Institute of New York city, and the Rayson Day Nursery of New York city.

CLINICAL MEMORANDA.

APPENDICITIS WITH APHASIA.

BY W. C. COLE, M.D.,
OF JACKSONVILLE, ILL.

On December 6, 1893, I was called to see Samuel A., about thirty-two years of age, who, though not rugged, had always enjoyed good health. He was suffering from severe abdominal pain, which was most intense in the right iliac region. His temperature was 100° F. I gave anodynes sufficient to control pain, a cathartic and febrifuges, and ordered hot applications externally. My diagnosis was perityphlitis. The active symptoms lasted about ten days, during which time anodynes were required for the pain; otherwise, the patient was treated tentatively. He made an uneventful recovery, though a hard tumor about the size of a small lemon remained in his right groin for several months.

On July 14, 1894, seven months afterward, he came into my office complaining of colic. Without much examination or questioning I treated him, and gave him instructions to keep as quiet as possible, and if not better soon to let me hear from him. Four days later I was called, and again found him suffering intensely from pain in the right iliac region. He had considerable fever. In the course of a week a well-defined enlargement was easily made out over the seat of the appendix vermiformis. The patient now had become somewhat delirious and was difficult to manage. He was having frequent rigors, and his temperature was 103° F. On August 1st I aspirated the tumor and withdrew three-fourths of a pint of creamy-looking pus, and on the following day repeated the operation, again removing considerable pus.

At this juncture the patient appeared to recover to a considerable degree from his delirium, and in its stead a condition of aphasia developed. Dr. C. E. Black then saw the patient with me. We opened the abscess cavity freely and washed it out thoroughly with an antiseptic solution, repeating the washings two or three times a day for about six weeks. A few days after the opening of the abscess symptoms of paralysis of the entire right half of the body began to show themselves. The right lower extremity became very painful, and the leg from the knee downward was very much swollen. The patient during these six weeks was unable to make himself understood, except by motions, grunts, and grimaces. The evacuations from the bowels and bladder were almost continuously involuntary for a period of three or four weeks. About two weeks after the operation a tender spot appeared on the bottom of the heel of the right foot, which continued to extend in size until finally an oval-shaped piece, two by four inches became gangrenous and sloughed to a depth almost reaching the bone. I should have stated that, preceding the delirium, the patient complained for several days of a severe headache, especially affecting the back part of the head and neck.

It is now two and one-half years since the man developed this condition, and he still has slight aphasia, being unable at times to call persons or things with which he is familiar by their proper names. He also complains of some numbness in the right hand and foot, and says they are nearly always cold, or colder than the other side of the body. We are unable to determine just what part of the brain is affected, but, following the description of similar cases in which autopsies have been made, we feel safe in saying that the lesion is located in the lower posterior third of the left side.

REPORT OF AN INTERESTING CASE OF PNEUMONIA.

By G. METZLER, M.D.,
OF PHILADELPHIA.

On April 28, 1897, at 8 A.M., I was called to see John B., six years of age, who complained of severe pain in the cardiac region. On examination of the chest there was seen in the region of the heart an area, about the size of a hand, discolored blue. As the boy complained so much of pain, and as the dyspnea was so severe, a further examination of the chest was not then made. A towel wrung out in cold water was wrapped around the chest, encircling it three times. This was covered by a piece of blanket of the same size. The effect of this application was remarkable; the pain ceased at once, and the patient fell asleep. His temperature at that time was 101.3° F. It was learned from the parents that he had vomited severely, which was probably the cause of the blue discoloration in the cardiac region, either from venous engorgement, or more likely from the rupture of a small venule.

The patient was again seen at 5 P.M., and it was then possible to examine the entire chest. This examination revealed the presence of an infiltration of the left lower lobe of the lung, with all the accompanying symptoms of croupous pneumonia. The wet application to the entire chest was continued, and, in addition, an icebag was placed over the cardiac region, because it was suspected that the pericardium was implicated in the inflammatory process. The heart sounds, clear in the morning, were somewhat muffled in the evening. Internally, one-sixteenth of a grain of calomel was given every hour, and one-half drop of tincture of aconite every three hours. The temperature was 104.3° F. The following morning the dyspnea was still intense. The boy complained of a little pain in the region of the heart. On examination of the chest it was found that the right lower lobe of the lung was also affected. In the evening the patient was more calm and the dyspnea less intense. It was learned that he had perspired a little. Temperature, 103° F.

The next morning, April 30th, the whole scene was changed. There was no dyspnea and no pain. His temperature was 101° F. There was a mitral murmur. The boy coughed now more than during the two previous days, and the sputum was streaked with blood. He was given tincture of digitalis (two drops) in elixir of cinchona, every three hours. The mitral murmur disappeared after three days.

The case seems worthy of note, because of its peculiar beginning, its rapid termination, and the decidedly beneficent action of the hydropathic treatment. In a disease so prevalent as pneumonia, and in which there is so little agreement between physicians as to the proper treatment, it seems that one is not only justified, but should be obliged to make public his experience in the treatment of just such cases as this one. Opium, venesection, dry or wet cups are recommended to relieve pain. I have used all these measures, and in some cases with good results. Bloodletting, however, in any form is not advisable in the case of a child; and as regards opium, this drug may be used, but if there are other measures which give equal beneficial results they should be used instead, as any interference with the excretory powers of the economy may lead to a fatal turn of the disease. In a disease which is determined in a few days, for good or for bad, it is all-important to keep the excretory organs in good condition, and, if need be, to stimulate them, so as to give free vent to the toxins circulating in the organism.

MEDICAL PROGRESS.

The Anatomy of the Ureters.—According to SCHWALBE in the *Centralbl. f. d. Med. Wissensch.*, Nov. 21, 1896, the human ureter is properly to be considered as having an abdominal and pelvic portion; in the former there is constantly present a fusiform dilatation lying just above the pelvic brim, called the greater dilatation. At its upper end, usually distant from the pelvis of the kidneys about seventy millimeters, is the narrowest part of the ureter, the "superior isthmus." At the junction of the abdominal and pelvic portions is the "inferior isthmus."

In the pelvic portion of the ureter, smaller fusiform dilatations can also be demonstrated. The right ureter is shorter, and has a more marked superior dilatation than the left. In the female these characteristics are more distinct than in the male. The two portions of the ureter join each other at an angle of 135°. This angle is a little sharper on the right side.

Investigations in quadrupeds show that in them the ureter has throughout a uniform caliber with no angle at the pelvic brim. In animals, which sometimes assume a vertical position—for instance, monkeys—there is a slight angle, and also a very slight fusiform dilatation above it. As a result of these observations, Schwalbe concludes that the superior dilatation is to be regarded as a compensatory dilatation, produced by the obstruction to the flow of the urine caused by the angle at the pelvic brim.

The Symptoms of Typhoid Lesions in the Large Intestine.—When the lesions of typhoid fever predominate in the large intestine they usually produce a group of symptoms from which it is possible to recognize this special localization of the disease. These cases are rare, and a diagnosis is seldom made. According to HENRIOT, an abstract of whose study of this subject appears in the *Gaz. Heb. de Med. et de Chir.*, Nov. 22, 1896, the following symptoms are characteristic:

1. Diarrhea is the most common symptom. It is profuse, often involuntary, and very fetid, presenting in general the characteristics of ordinary typhoid stools, though these may be more watery and have less color.

2. Meteorism is a less valuable symptom, as it occurs in numberless cases of typhoid fever with lesions in the small intestine.

3. The pain is located sometimes at one point and sometimes at another, and sometimes throughout the whole course of the large intestine. This symptom is rarely absent when there are ulcerations, but it is often necessary to examine the patient with reference to its existence, and in certain cases abdominal pressure reveals its presence, although the patient does not complain of any tenderness if not disturbed.

4. The general condition is very bad.

The prognosis in these cases is unfavorable.

THERAPEUTIC NOTES.

For Renal Colic.—

℞	Lycetol	gr. xv
	Bicarbonate of soda	gr. viiss

M. Ft. Chart No. 1.

To be taken morning and evening, dissolved in a glass of mineral water.—*Wittzack.*

How to Administer Oily Enemata.—Oil has of late been administered by the rectum with good results to patients worn out by wasting diseases. The best method of administration is not yet agreed upon. Deucher, who has experimented extensively along this line, reports in the *Semaine Medicale*, April 9, 1897, that the maximum of absorption is attained with an emulsion of equal parts of oil and a solution of sodium carbonate to which is added a little sodium chlorid. The whole is administered at the temperature of the body.

An Efficient Application for Psoriasis is the following:

℞	Chrysarobin Ichthyol } aa	gr. xx
	Acid salicylic	gr. viii
	Oxid of zinc ointment	ʒ iiiss
	Vaselin	q.s. ad ℥ i

M. Sig. Remove scales and rub in ointment for half an hour. Leave the ointment on during the night and bathe in the morning.—*Unna.*

A Useful Combination for the Pain of Herpes Zoster:

℞	Alcohol	℥ i
	Menthol	gr. xv
	Ext. cannabis indica	gr. xxv

M. Sig. Apply by means of pads made of wadding, which should be frequently renewed during the day.—*Leloir.*

Furunculosis is benefited by the following plaster:

℞	Acid salicylic	ʒ ii
	Soap plaster	℥ ii
	Diachylon plaster	℥ i

M. Sig. Apply spread on cloth.—*Heitzman.*

An Excellent Application for Pruritus of the Vulva:

℞	Chloroform	ʒ ii
	Amygdalin oil	℥ ii

M. Sig. Apply as necessary.—*Scanzoni.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, MAY 22, 1897.

THE MALT EXTRACT OF THE PHARMACOPEIA AND THE MALT EXTRACT OF THE STREET-CARS.

AN interesting article by Harrington, published in the *Boston Medical and Surgical Journal*, December 31, 1896, reminds us that the term malt extract was originally used to denote a honey-like substance extracted from malted barley, containing no alcohol, but having a high percentage of sugar and dextrin, and about two per cent. of the ferment diastase, one part of which will convert 2000 parts of starch to glucose and dextrin. On account of the last property it has been widely prescribed to assist the digestion of starchy food.

But this old definition of a malt extract, owing to the efforts of the brewers, has recently given way very largely to the idea that a malt extract is a liquid preparation, more or less effervescent, to be drunk by the glass or *ad libitum* with meals or on retiring. The value of these preparations in digestive, respiratory, nervous, and other troubles, and especially as a food for nursing mothers, is alleged with great vehemence in advertisements, while in every street-car are pictures of opera-singers, actors, professional beauties, athletes, warriors, and statesmen of both the Eastern and Western hemispheres, who attribute their success in life to the unstinted use of one or the other of these preparations. An analysis of twenty-one of these extracts as made by Harrington is so instructive that it is printed in full:

TABLE I.

Brand.	Specific Gravity.	Alcohol.	Total Residue.	Ash.
Beefmalt	1.0523	1.56	13.066	0.428
Gahm's Malt Extract	1.0156	6.07	6.328	0.232
Hercules Malt Wine	1.0378	6.07	11.634	0.528
Herculine Extract of Malt	1.0149	3.29	5.130	0.202
Hoff's (Eisner & Mendelsohn)	1.0313	2.56	8.187	0.197
Hoff's (Tarrant's)	1.0288	4.37	6.862	0.262
Leicester's English Malt Extract	1.0263	2.83	8.040	0.238
Liquid Bread	1.0168	5.37	6.180	0.214
Malt-Nutrine	1.0555	0.74	13.630	0.250
Malt Wine (Haffenreffer & Co.)	1.0279	4.25	8.666	0.200
Menzel's Extract of Malt	1.0193	3.59	6.310	0.280
Mulford's Digestive Malt Extract	1.0196	1.31	6.632	0.250
Noris Extract of Malt	1.0387	3.88	11.455	0.256
Old Grist Mill Malt Extract	1.0383	3.82	11.060	0.260
Pabst Malt Extract	1.0280	4.10	8.666	0.312
Pasteurized Extract of Malted Barley	1.0156	3.88	5.280	0.230
Puremalt	1.0271	5.56	8.436	0.466
Teutonic	1.0286	6.28	9.458	0.398
Vitamalt	1.0222	4.69	7.206	0.264
Wampole's Extract of Malt	1.0257	7.13	9.534	0.386
Wyeth's Extract of Malt	1.0540	1.37	12.656	0.390

Diastase absent in all of the above brands.

TABLE II.

Brand.	Specific Gravity.	Alcohol.	Total Residue.	Ash.
Milwaukee Beer	1.0173	4.12	6.220	0.182
Culmbacher Beer (Domestic)	1.0305	5.06	9.742	0.362
Pale Ale (English)	1.0064	5.62	4 080	0.344
Porter (Irish)	1.0151	6.14	6.194	0.474

It will be observed that no one of these preparations contains a trace of diastase; that six of them contain over five per cent. of alcohol (more than ordinary beer contains), while only six of them have more sugar than domestic beer. Many of them contain salicylic acid. From an economic standpoint they possess no advantage over beer, ale, or porter. On the contrary, according to the size of the bottle and price asked, the consumer obtains for ten cents from 100 to 250 c.c. of malt extract; of imported ale or porter he obtains from 220 to 260 c.c., while of domestic beer he receives from 800 to 840 c.c.

THE NEW YORK UNIVERSITY BELLEVUE HOSPITAL MEDICAL COLLEGE—ORGANIZATION OF THE FACULTY.

THE announcement of the names of the men who will compose the faculty of this newly organized medical school has been awaited with no little expectancy, not only by the parties particularly interested, but by the whole profession. It was recognized by all that the selection of a faculty was, under the circumstances, a most delicate procedure. There was no dearth of material; on the contrary, the situation that confronted the appointing power was *l'embarras de richesses*. It was impossible to find positions for all the members of the two original organizations.

The point about which the keenest interest centered was whether the Council would be guided in each selection by the uncompromising spirit of the best man for the place, or whether its judgment would be swayed by such considerations as family and finance. The terms under which the consolidation was affected guaranteed fair and considerate treatment of both organized parties to the contract, and yet the necessities of the case demanded compromise. In such transactions the danger is that in the effort to satisfy all no one is pleased.

The plan adopted by the Council was a somewhat novel one, and displayed a master stroke of diplomacy in shifting the responsibility to the shoulders of the former professors and making each one of them actually elect, not only himself, but his fellows. This was accomplished by inviting each professor to send in a confidential ballot nominating members of a complete faculty, it being understood that he himself was already in nomination for his own chair. The selection was not to be limited to the faculties of the two colleges, or to New York city. Nominations were thus made for the forty-one professorships in the nineteen departments of the consolidated institution. In the two faculties there had been fifty professors. The result of the balloting was that nine-tenths of the faculty chosen by the university corporation received the support of a majority of both the old faculties. Six members were made professors emeritus, five of whom were active professors last year.

In a delicate negotiation of this nature it is inevitable that there will be some disappointments, but, on the whole, it must be acknowledged that the Council has met the ordeal in a manner that commands the approval of every candid critic.

This new institution may now be considered organized; it only remains to adjust the details of its domestic economy, adapt its present buildings to the new exigencies, and erect such additional structures as the new conditions require.

Extensive plans for new buildings are under consideration. Since the consolidation of the two colleges, the University has acquired a large additional plot of ground on Twenty-fifth street, just south of the buildings already owned by it. This plot measures 100 feet in depth by 175 feet in length. The plan for its improvement contemplates two courts with an east building, a center building, and a south building. The center and east buildings will be erected soon.

Henceforth New York city will possess two of the largest and best-equipped medical schools in this country, if not in the world: the College of Physicians and Surgeons on the west side of the city and the newly organized institution on the east side. Each is provided in its immediate vicinity with ample hospital facilities and abundant clinical material; each one has allied itself with a strong and wealthy university; the requirements for admission and graduation are equally exacting, and on the parallel lines along which they must inevitably develop, a healthy, generous rivalry will stimulate to the loftiest ambitions and the noblest aims.

ECHOES AND NEWS.

A New Remedy for Gout.—An English physician claims that regular daily traveling in railway cars has a hygienic value, and is especially beneficial in cases of gout.

The International Congress at Moscow.—It is announced that the Russian railways have generously decided to grant free passes to members of the Congress, thus greatly reducing the expenses of the journey.

A "Kneipp Cure" Sanitarium in Vermont.—The American Kneipp Cure Company of New Jersey, proposes to open its first Kneipp-cure sanitarium at Middletown Springs, Vt. The company is capitalized at $1,000,000. Middletown Springs is now a popular summer resort known for pure air and water, and the Kneipp-cure people propose to change the name to Kneippville.

The New York Morgue-Keeper Found Guilty,—The Board of Charities has reached a decision in the case of Morgue-Keeper Albert M. White, who was tried by the board three weeks ago on a charge preferred on December 5, 1896, that he had illegally disposed of bodies committed to his care. The members of the board are unanimous in the decision that White is guilty as charged, and they have dismissed him from his position.

Extraordinary Death of a Physician.—Dr. Carrier of Varennes, France, has recently died under painful circumstances. The daughter of a patient to whom he had given a hypodermic injection of morphin, seeing her mother very quiet, thought she was dead, and cried out that the doctor had poisoned her. Dr. Carrier was seized with a fainting fit, and, as he fell, struck his head against the mantelpiece, receiving injuries which resulted in his death a few hours later, just as the patient awoke, much relieved by her peaceful sleep.

The Roentgen Ray in Surgery.—At the Instituto Fisico of the university at Pavia, Italy, the entire tibia of the left leg of a boy patient having been removed, a series of object lessons on the reproduction of the lost bone were initiated, with the help of the Röntgen ray. The organic functions of the osseous tissues, as illustrated in the reproductive process, were watched and registered at stated intervals, and the value of the Röntgen ray in surgical diagnosis and treatment, and equally in surgical teaching, was vindicated in the most striking manner.

Report of New York Prison Commission.—In the recent report of the State Commission on Prisons regarding the condition of the penal institutions of New York city are some statements of unusual interest. The investigation revealed the fact that only five per cent. of the youths between the ages of sixteen and nineteen awaiting trial before the courts of New York are sent to the Tombs. Ninety-five per cent. of these youthful offenders are cared for by Mr. Gerry's society. In the Kings County Penitentiary, the commission reports, the bath-rooms are new and excellent, being so arranged that, while forty may bathe at the same time, each person is in a separate booth, or stall, with a separate dressing closet for each; yet all are subject to the surveillance of the keepers. The plan could well be copied in other prisons.

Parrots as Sources of Tubercular Infection.—Bronchopneumonia has assumed almost an epidemic form in Genoa, Italy, caused, it is believed, by infected parrots brought from Brazil. Fourteen persons have been attacked by it, and eight have died. The susceptibility of the parrot to all lung diseases, above all to tuberculosis, is being widely discussed by the medical journals. In Berlin the profession has long been alive to the danger of harboring and petting the parrot, as the malady is often hereditary in the bird, and is aggravated by the close confinement of the voyage to Europe—even after arrival it is, for the most part, exposed to unsanitary conditions, under which it contracts tuberculosis and bronchopneumonia from human sufferers from these ailments. The Veterinary School has had 154 parrots under observation, and fifty-four of them have been found, by bacteriologic tests, to be suffering from advanced tuberculosis.

Mr. Lawson Tait and Hospital Abuse.—The Birmingham *Daily Post* gives Mr. Lawson Tait's views on hospital reform: "We (the profession) are entirely responsible for hospitals, and for all their faults as well as their merits." He maintains that the medical officers of the Birmingham Hospital could make an end of the trouble in a month. As a temporary expedient, he suggests that they should assign thirty per cent. of their income accruing from hospital positions for the assistance of their "struggling extramural brethren." The *Lancet*, commenting on this says: "We are sure the 'struggling brethren' would decline any such remedy. All they ask from their hospital colleagues is to use their influence to restrict the benefits of hospital treatment to those who need it and cannot afford to pay for it. Neither is it of any use to lay the whole blame on hospital honorary officers. The committees and governors of hospitals are equal, or greater culprits."

Obituary.—Dr. George W. Burdett died in Clinton, Mass., May 10th. He was seventy-six years of age, and was a graduate of Dartmouth Medical School and of Harvard Medical School. He was for many years a member of the Board of Directors for the Bigelow Free Public Library, and had been Master of the Trinity Lodge of Free and Accepted Masons.—Dr. Elisha Munger of New London, Conn., died May 14th, after ten weeks of suffering, following an operation for appendicitis. He was forty-nine years old, and for a quarter of a century practised medicine in New London county, commencing at East Lynn, and afterward removing to the city, where he had lived for nine years.—Dr. Magitot, who was the founder in France of modern dentistry, and wrote many important works upon the development of the teeth, died recently very suddenly during an attack of angina pectoris. He was a member of the Academy of Medicine, and had been president of the Society of Anthropology.—Mr. Louis Pascal Casella died at Highgate, England, April 23d, aged eighty-six years. Mr. Casella was the first to construct a registering clinical thermometer.

A Controversy in the Medical Society of New Haven, Conn.—On the Faculty of the Yale Medical School is Dr. B. A. Cheney, whose father is a homeopathic physician. The younger physician has made repeated attempts to become a member of the regular local society, and, it is asserted by his friends, has been unjustly kept out on the alleged ground of homeopathic affiliations. One of the prominent physicians opposing Dr. Cheney's admission has been Dr. F. E. Beckwith of New Haven, one of the leading obstetrical specialists in the State, and formerly connected with the Yale Medical School. At a recent meeting of the Medical Society Drs. Osborne and L. W. Bacon of the Yale School, as a counter-thrust, and with the evident intent of carrying the war into Africa, preferred charges against Dr. Beckwith of consultation with local homeopathic physicians. The charges were referred to a committee of three, which found that Dr. Beckwith had consulted with homeopaths only in emergency cases, and reported by a majority vote in his favor, one of the committee, however, favoring expulsion. The vote of the society stood 33 to 17 in Dr. Beckwith's favor. A striking feature of the case was the appearance of Dr. Francis Bacon as leading defender of Dr. Beckwith, while Dr. L. W. Bacon, his nephew, in the Yale Medical School, led Dr. Beckwith's foes. To a disinterested observer the affair has the flavor of a tempest in a teapot, and carries the earmarks of personal retaliation.

MEETING PLACES.

General Meetings, Academy of Music; hours, 10 A.M. to 1 P.M. daily.

Registration Office, Horticultural Hall (lower corridor).

Post-office, Horticultural Hall (outer vestibule).

SECTIONS.

Practice of Medicine, Broad Street Theater.

Surgery and Anatomy, Horticultural Hall (lower hall).

Obstetrics and Gynecology, Beth-Eden Church.

Neurology and Medical Jurisprudence, Beth-Eden Church (upper room).

Ophthalmology, Hotel Walton (tenth floor).

Laryngology and Otology, Hotel Walton (tenth floor).

Materia Medica and Pharmacy, Academy of Music (Blue Room).

Diseases of Children, Academy of Music (Foyer).

State Medicine, Academy of Music (Red Room).

Dermatology and Syphilography, Horticultural Hall (Foyer).

Physiology and Dietetics, Hotel Stenton.

Dental and Oral Surgery, Hotel Walton (Parlor D).

All Sections meet at 9 A.M. and 3 P.M.

The exhibition of books, pharmaceutical preparations, and surgical instruments will be given in the main hall, Horticultural Hall, immediately adjoining the Academy of Music.

Notes of Interest Regarding the Coming Meeting of the American Medical Association at Philadelphia.—The semi-centennial meeting of the American Medical Association will take place at Philadelphia on Tuesday, Wednesday, Thursday and Friday, June 1st to 4th. The general meeting will be opened on Tuesday by the introduction of the venerable Dr. Nathan S. Davis, of Chicago, attended by the presidents of the State medical societies, and he will deliver an address, entitled "A Brief History of the Origin of the American Medical Association, the Principles on which it Was Organized, the Objects it Was Designed to Accomplish, and How far they Have Been Attained during the Half-Century of its Existence." The President of the Association is Dr. Nicholas Senn of Chicago, and the First Vice-President Surgeon-General George M. Sternberg.

It is expected that nearly 3000 delegates will attend this memorable meeting, and the profession of Philadelphia has made great preparations for their reception, not only from a social, but even more particularly, from a scientific standpoint. Arrangements have been made for special courses at the various colleges so that delegates may, however briefly, become acquainted with recent medical processes. The committee in charge has found it possible to arrange for the general and sectional meetings to take place in the buildings situated within a single block on Broad street, *i. e.*, that block extending from Locust street to Spruce street. The position of these various buildings, and of the different hotels which offer special rates to the members of the Association, is shown on the accompanying map, which may prove of much use to those readers of THE MEDICAL NEWS who intend to be present at the meeting. At the southeast corner of Broad and Locust streets is situated the Hotel Walton which will be the headquarters of the Association and in which three of the sections will meet. Immediately adjoining it to the south is the Broad Street Theater with a large seating capacity which will be devoted to the Section of Practice of Medicine. Adjoining it to the south is the Hotel Stenton in which the meetings of the Section of Physiology and Dietetics will be held. Immediately opposite, at the northwest corner of Broad and Spruce streets, is the Beth-Eden Church, which, in addition to its ordinary accommodations, contains a large meeting-room. This building will be used by the sections of Obstetrics and Gynecology, and of Neurology and Medical Jurisprudence. Immediately across from the Broad Street Theatre is Horticultural Hall, a newly erected building, exceedingly handsome in its inside and outside decoration, the main hall of which will be devoted to exhibition purposes. This hall also contains two large meeting-rooms which will be devoted to the sections of Surgery and Anatomy and of Dermatology and Syphilography. Finally, the Academy of Music, immediately adjoining Horticultural Hall, and which is capable of seating nearly 3000 persons, has been engaged for the general meeting. Smaller rooms in the same building will be used for the sections of Diseases of Children, of Materia Medica and Pharmacy and of State Medicine.

These places of meeting are also situated close to the College of Physicians at the corner of Locust and Thirteenth streets, an institution which has the largest medical library in the United States next to that of the Surgeon-General's Office at Washington, Most of the important clubs are also within a few hundred yards of the hotel headquarters. It will also be noticed that the meeting places are but three blocks away from the Broad Street Station of the Pennsylvania Railroad and but four blocks from the Terminal Station of the Reading Railroad.

Several luncheons will be given each day under various auspices. The dinners of the various sections will take place on Tuesday evening at 7 o'clock, and on Wednesday evening the University of Pennsylvania, the Union League Club, Jefferson Medical College, the Academy of Fine Arts and other institutions will hold receptions. On Thursday afternoon the Provost of the University of Pennsylvania, Mr. C. C. Harrison, will receive the delegates on the campus of the University, and several private lunches will also be given on the same day. The publishers of the MEDICAL NEWS, Messrs. Lea Brothers & Co., have invited the visiting delegates and their wives to a theater-party on Thursday evening, at the Broad Street Theatre, at which refreshments will be served. On Friday the Philadelphia Medical Club will give a luncheon at the Hotel Aldine, and on that afternoon the meeting will come to a close.

Vital Statistics in England and Wales.—The Registrar-General of Births, Deaths, and Marriages in England and Wales has just issued his report for 1895. The following are some of the more generally interesting facts contained in it. The population was 30,383,047—14,721,820 males and 15,661,227 females. The number of marriages registered was 228,204, corresponding to a rate of 15 persons married per 1000 living, against 15.1 per 1000 in the previous year, and an average of 14.9 in the ten years 1885–'94. The slight fall in the marriage-rate, as compared with that of 1894, was accompanied by a rise of 4 per cent. in the value of British exports, a rise of 1 per cent. in the value of imports, and a rise of 1 per cent. in the average price of wheat per quarter. Of the 228,204 marriages, 156,469, or 686 per 1000, were celebrated according to the rites of the Church of England, and 71,735, or 314 per 1000, otherwise. These proportions are exactly the same as those of 1894. Of each 1000 men married during the year 1895, 891 were bachelors and 109 widowers; of each 1000 women married, 924 were spinsters and 76 widows. The births registered during the year numbered 922,291, and were equal to a rate of 30.4 per 1000 persons living, or .8 below the average rate in the preceding ten years. The births of males numbered 468,886, and the births of females 453,405, the former bearing to the latter the proportion of 1034 to 1000, against an average proportion of 1037 to 1000 in the preceding decennium. The excess of male over female births has shown a general tendency to decline ever since the year 1841. The deaths registered during the year numbered 568,997, and were in the proportion of 18.7 per 1000 of the population. Although the rate showed an increase of 2.1 per 1000 upon the unprecedented low rate of 1894, it was slightly below the mean rate (18.9) of the ten preceding years 1885–'94. The 568,997 deaths included 290,704 males and 278,293 females. The death-rate among males was therefore equal to 19.7, and that among females to 18.7 per 1000 living of the corresponding sex. Out of equal numbers living there were 1111 deaths of males to 1000 deaths of females, against a mean proportion of 1121 in the ten years 1885–'94.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

JEFFERSON MEDICAL COLLEGE COMMENCEMENT—CLASS-DAY EXERCISES AT THE MEDICO-CHIRURGICAL COLLEGE—DR. W. S. HALSTED—A PAY-HOSPITAL FOR CONTAGIOUS DISEASES—A SUMMER LABORATORY COURSE.

PHILADELPHIA, May 15, 1897.

THE seventy-second annual commencement of the Jefferson Medical College was held in the Academy of Music on May 14th, and the degree of Doctor of Medicine conferred upon 161 members of the graduating class by the Hon. William Potter, President of the Board of Trustees. The opening prayer was made by the Rev. Allen B. Philputt, D.D., and an address was delivered by the Rev. Francis L. Patton, President of Princeton University, whose remarks contained much that may be remembered with profit by the newly graduated physicians. Prof. E. E. Montgomery gave the valedictory to the class. He spoke of the value of the graded curriculum which they had followed, contrasting its advantages with the training received by medical students in years past, and referred to the long list of men famous in medicine and in surgery, who have helped to give to their *alma mater* her enviable position among medical schools.

The annual banquet of the Alumni Association of the Jefferson Medical College was given on the evening of May 13th, at the Hotel Bellevue. Dr. H. A. Hare, the toastmaster of the evening, introduced Mr. James P. Townsend, who spoke for the Board of Trustees. Dr. A. H. Hulshizer made a report on the fund for the equipment of the new pathological laboratories of the college, which showed that a total of $7000 had been subscribed for this purpose. Other speeches were made by Dr. George McClellan, who responded to the toast, "The Alumni Association"; by Mr. Hampton L. Carson, giving a sketch of the famous medical men of Philadelphia from Penn's time to the present day; by Prof. W. W. Keen, for the faculty; by Prof. H. A. Wilson, for the clinical faculty, and by Dr. E. Q. Thornton, on behalf of the demonstrators of the college. Several hundred alumni were present, and the banquet was considered one of the most successful ever held.

As a prelude to the commencement exercises of the Medico-Chirurgical College, to be held next week, the Class-Day exercises of the graduating class of this institution were observed on May 13th. Speeches were made by Prof. Isaac Ott, Dean of the Faculty, and by Messrs. A. C. Morgan, the Class President; J. A. McKenna, the Class Historian, and A. C. Buckley, the Valedictorian.

A dinner and reception were given to Dr. William S. Halsted of Baltimore, on May 13th, by Dr. W. W. Keen, at the University Club.

At a meeting of the Philadelphia County Medical Society, held on May 12th, Dr. J. Madison Taylor, Chairman of the Joint Committee of the County Medical Society, and the Woman's Health Protective Association of Philadelphia, on the proposed pay-hospital for contagious diseases, made a report of the work accomplished by this body toward securing this much-needed institution. The site recommended for the hospital is that at present occupied by the Municipal Hospital for Contagious Diseases, in a section of the city where, by reason of the proximity of two railroads, a residence neighborhood is unlikely to be built up. The need of a pay-hospital of this kind, where patients may be attended by their own physicians, was shown to exist, and encouraging progress in the movement was reported.

Dr. Edward Rosenthal read a paper on "The Municipal Hospital of Philadelphia," in which he described the new diphtheria pavilion, which has recently been added, and suggested other improvements, notably a building for suspected cases, and also the purchasing of more ground adjacent to the institution, to be used temporarily as a park for the patients. In the discussion of Dr. Rosenthal's paper, a communication from Dr. Benjamin Lee was read, highly praising the diphtheria pavilion, and suggesting that, as the State Board of Health had decided to place measles among the diseases to be quarantined, a building for this class of patients should be provided, in order to prevent their coming in contact with other contagious diseases. Dr. William Welch spoke of the need of money for necessary improvements at the Municipal Hospital, and urged that smallpox cases be cared for in a building in some remote locality. On motion by Dr. John Ashhurst, Jr., a committee was appointed to draft a resolution of the Society's approval of the present site of the Municipal Hospital, and requesting the city councils to make more liberal appropriations to carry on the work of treating the city's cases of infectious disease.

A summer laboratory course, lasting from May 1st until July 1st, has been inaugurated at the Medico-Chirurgical College, under the direction of Prof. Joseph McFarland. The work, which is open to both undergraduate and post-graduate students, includes bacteriology, morbid anatomy and histology, autopsies, toxicology, medical chemistry, and clinical microscopy.

OUR VIENNA LETTER.

[From our Special Correspondent.]

KOCH'S RECENT PUBLICATION ON TUBERCULIN AND AUSTRIAN OPINIONS OF IT—THE THYROID AND CONGENITAL ANOMALIES—THE BOTANIC SPECIFIC PATHOGENEITY OF MICROBES TO BE DISCUSSED AT THE INTERNATIONAL MEDICAL CONGRESS AT MOSCOW—VASELIN FOR ERYSIPELAS—DOCTORS' FEES IN VIENNA.

VIENNA, April 15, 1897.

THE interest displayed in Vienna in Koch's latest publication on tuberculin and its diagnostic and therapeutic possibilities serves to show the prominent position the "Dean of Bacteriology" occupies in the German medical world. Every one of the many Viennese medical journals published detailed abstracts from the report within a few days of its appearance, and most of them in addition had editorial comments. The very limited applicability, as far as therapeutics are concerned, claimed for the tuberculin, even by its inventor, seems to be a source of general disappointment. The proofs of its diagnostic value very early in the course of tuberculosis, before the slightest positive physical signs are present, are very cordially welcomed. Vienna, whose death-rate from tuberculosis is comparatively very high, ought to furnish an excellent field for the confirmation and further development of this part of the master's work.

The attitude of the political press in the matter seems worthy of note. Most of the papers have printed notices and comments, but usually in but few words. Some of them, however, do not seem ready to forget their overreaching enthusiasm when the first announcement of the discovery of tuberculin was made some six years ago, and the melancholy disappointment which followed it. There have been some sarcastic comments. One of the journals suggests that the date of the publication, April 1st, is not without significance, and that it is not this time to be taken too seriously. One of the comic papers, in a rhymed skit, announces a cure for tubercle, but not in men; only in rabbits and guinea-pigs. It is the old story the world over: the public generally cannot appreciate the slow and sure progress of true science, but demand immediate results and carp at the little that each advance really means while there still remains so much to be done. Notoriety is the earmark of humbug, and the press, in default of something better, is ready to exploit the latest medical fad or the pet theory of someone who is not as visionary as he seems, but has an eye only for the main chance. It is reassuring and not wholly without a sense of compensatory universality that one finds that the spirit is not confined to America alone.

The rôle of the thyroid or parathyroids would seem, according to a series of observations reported to the Vienna Medical Society on April 5th, to be even wider than that so far accorded them. Nearly all the cases of dwarfed development that came under the observer's notice, even when seemingly entirely unassociated with any symptoms of myxedema, had as an accompaniment errors of development of the thyroid. Many congenital anomalies, especially the more serious ones, would seem to be likewise associated with defects, either atrophic or hypertrophic, of this important gland. Something of this may be due to the fact that effect is taken for cause, and that anomalies of the thyroid, by defect or exaggeration, are present when other anomalies occur; but there seems in addition to be good grounds for thinking that the glandular malformation is primary and causative.

The question of the botanic specificity of microbes, which is to take up some of the attention of the coming International Medical Congress at Moscow in August, is, to all appearances, going to bring out a series of striking contributions to the principles that underly the infant science of bacteriology. Not all of them will be confirmatory of a number of theories that have so far been generally accepted. There is even more than a hint given that some of the papers will be rather revolutionary in character, and that the basis on which a good deal of work has been done as regards the specific pathogeneity of certain bacterial forms will be materially modified, and perhaps entirely swept away.

The position of the French school, especially of the great bacteriologists at the Pasteur Institute—Duclaux, Metchnikoff, and Roux—with regard to the specific pathogeneity of certain bacterial forms that have, until recently, been universally accepted as undoubtedly specifically causative of disease is well known. The cholera and typhoid bacilli, perhaps even the diphtheria bacillus, and others, would seem to have lost some of the reputation for specificity that has been accorded them so long.

The Austrian school, as represented here at Vienna, would seem to have decided tendencies in the same direction. Closely in touch as they are with German scientific matters all over the German Empire, because of a common mother-tongue, the Vienna school may be looked upon as understanding thoroughly the state of mind generally of German-speaking bacteriologists. There is an almost universal air of expectancy in the matter, and hints are dropped of interesting developments. The outcome cannot fail to be of unusual interest for scientific medicine generally and bacteriology and hygiene in particular.

A series of cases of erysipelas treated with applications of simple vaselin, with excellent results, have just been reported to one of the medical journals here. One can look at the report in two ways, I suppose; either vaselin has been developing therapeutic properties hitherto undreamed of (and then one could accept the report seriously and proceed to treat his next case of the disease in this way, with good or ill success according to whether his state of mind is distrusting or confiding), or one might remember that erysipelas, being as a rule self-limited and running a definite course, has enjoyed the privilege of having at one time or another half the drugs in the pharmacopeia vaunted as specifics for it, and so let the matter drop. Meantime, it is encouraging to find that it is not only in America, completely benighted medically as it would seem to be to most German and Austrian medical men, that long-since exploited therapeutic measures find their way into the medical journals with the specious testimony of a series of cases which test their value.

A good deal of attention has been devoted in the medical journals here, and by the public generally, to the question of doctors' fees. Until a recent decision of the *Arzt-Kammer*, there has been no regularly recognized fee for medical services in Austria. A legal decision was given some fifty years ago, I believe, when money was of much greater value than it is now, which empowered the physician to collect 50 kreutzers (about 20 cents) for each professional visit. The taking of legal steps for the collection of a bill has been generally looked upon as almost, if not quite, unprofessional. The *Arzt-Kammer*, a sort of representative body that in different districts in Austria regulates the relations of physicians with each other and with their patients, and has power to make certain rules and inflict certain penalties, has lately attempted to obviate some of the difficulties that almost necessarily arose under this state of affairs by announcing the legal fee that a doctor could demand for a professional visit within a certain radius. The amount was set at 3 gulden ($1.20), though less could be asked where the circumstances of the patient would not allow him to pay this much. The decision has raised a storm of comment, a good deal of it being unfavorable. The public does not seem to like to be reminded that physicians' fees are rights and not merely the material expression of a grateful patient's feelings. Some of the doctors have been inclined to think the decision inopportune, while others have expressed the opinion that the fixing of the fee, though at the price that it has been the custom generally to give and ask, would react against the physicians themselves and really lessen the amounts that might be paid by certain patients. To an outsider this does not appear probable, while the definite fixing of a fee would seem to have its advantages.

The discussion brings out the fact, however, that physicians are even worse paid here than among ourselves, and a profound feeling of justifiable dissatisfaction at the state of affairs has taken hold of the profession. The comparison with the honoraria paid to other professional men is not calculated to lessen this feeling. As has been said here, "In no profession is there such a disproportion between the quality and amount of work done and the reward obtained. Taking merely the material labor, how many visits must not a doctor make, and how many steps must he not climb for 1000 gulden! Yet he is, and must be, one of the most highly educated of professional men." It would seem as though the world-wide dissatisfaction in this connection must lead very soon to the development of a better state of mind in the general public as regards the rewards to be given the physician for his skill and labor.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Twelfth Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

(Continued from page 617.)

THIRD DAY—MAY 6TH.

THE RELATION OF NEURASTHENIC CONDITIONS TO THE GENERAL NUTRITION,

was the title of a paper by DR. R. T. EDES of Jamaica Plain, Mass.

He held that gain in body weight and improvement in neurasthenic symptoms usually go together, but that there are enough exceptions to the rule to show that the nervous nutrition is something more than a mere sample of the general. The more symptoms approach in character the "fixed idea" of the insane the less amenable are they to the beneficial effect of mere somatic therapeutics. The blood color of a considerable number of neurasthenic patients corresponded quite closely with that of the employees in the same institution. It is not possible to establish any correspondence between the degrees of anemia and the intensity of nervous symptoms. Measurements of the excretion of uric acid afford no sufficient ground for supposing that neurasthenic symptoms depend in any way upon this substance. There may be such a thing as a chronic uric-acid headache, but the ordinary continued neurasthenic headache is not of this character. Indican determinations have not been numerous enough to be decisive, but do not seem to indicate that the poison consists in this substance or in those which may be transformed into it. If neurasthenia is a toxic condition, the poison has not yet been satisfactorily identified.

DISCUSSION.

DR. JAMES J. PUTNAM corroborated the statement that patients might look very pale and yet have a normal percentage of hemoglobin. As to the influence of uric acid upon the causation of the disease he is still in doubt. It is not safe as yet to give a name to the agent which causes the condition, but we are learning more and more every day that the pathology of nervous disturbances may be connected with changes in metabolism. Study of cases of epilepsy must cause a good deal of doubt to arise as to whether the changes which are found are the cause of epileptic attacks or the result of them.

A paper, entitled

REFLEX NEUROSES OF THE ABDOMEN,

was read by DR. NORMAN BRIDGE of Los Angeles, Cal.

The paper set forth, from a clinical standpoint, a large number of cases of reflex neuroses or symptoms, such as urticaria, pruritus ani, convulsions in children, etc., which were simply reflex manifestations of abdominal disorders. He desired to call attention to the fact that these symptoms are often reflex in origin, for they are frequently overlooked, and often tend to confusion in diagnosis.

DISCUSSION.

DR. CHARLES G. STOCKTON said that the "postprandial diarrhea" of which Dr. Bridge had spoken occurs with sufficient frequency to entitle it to a special name. In addition to the hurried evacuations, there is almost invariably a gastric anacidity. These two symptoms are peculiar. In each of the cases which he had seen there were striking errors in the accommodation of the eyes. He did not mean to assert that these conditions were dependent upon this ocular error, but he thought it had some influence. A second point which he wished to refer to was the subject of pigment neuroses. These can often be explained by some condition of the stomach, intestines, or kidneys, and he had seen relief of this condition follow the replacement of a displaced kidney.

A paper on

THE ROENTGEN RAYS IN THORACIC DISEASE,

was read by DR. FRANCIS H. WILLIAMS of Boston.

This paper was a sequel to one presented by the author at the last meeting of the Association, and illustrated the progress which a year has witnessed in the utilization of these rays. The paper was illustrated with skiagraphs showing diseased conditions of the lungs and heart. The rays were especially serviceable in pneumonia, pleurisy, and tuberculosis of the lungs, enlarged heart, and pericarditis with effusion. Skiagraphs of the leg were also presented, showing not only the bones, but also the tendons, nerves, and blood-vessels.

DISCUSSION.

Dr. Fitz of Boston showed several skiagraphs of two cases of aneurism of the aorta. The question had been raised of the transmissibility of the X-rays through calcareous substances, but he had succeeded in illustrating the possibility of photographing renal calculi. These rays also make possible the diagnosis of obscure cases of pelvic disease.

A CASE OF ACROMEGALY

was reported by **Dr. O. T. Osborne** of New Haven.

Dr. W. H. Welch of Baltimore introduced Dr. Osborne, who is not a member, to the Association, and asked that he be allowed to present some pathologic specimens from a case of acromegaly which had been under his care, the patient having recently died. The patient had had the disease twenty-three years, and two photographs—one taken in 1887 and the other in 1892—gave a graphic description of the progress of the disease during that time. The man was 5 feet 9 inches in height, and had a marked kyphosis, which took several inches off his stature. At death he weighed 300 pounds. The brain was normal, but the heart was enormously enlarged, weighing 2 pounds 9 ounces—one of the largest hearts on record. The thyroid weighed 101 grams, but contained only one-twentieth of the normal amount of iodin. An internal thyroid was found, very much smaller than the other, but containing twice the amount of iodin. Photographs of the different parts of the skeleton, placed side by side with corresponding portions of the skeleton of a normal 6-foot man, were exhibited, and showed very clearly the enormous increase in the size of the bony skeleton.

THE CHEMICAL PROPERTIES OF THE BLOOD-PRESSURE-RAISING CONSTITUENTS OF THE SUPRARENAL CAPSULE,

was the title of a paper by **Dr. John J. Abel** of Baltimore.

Dr. Abel described the fruitless efforts of Vulpian and more recent investigators to isolate the chemic constituents of the suprarenal capsule that gave to it its blood-pressure-raising power. He then told of his experiments in the same line, and described the technic by which he finally succeeded in isolating what appeared to be the active principle of the suprarenal capsule from an aqueous solution of the gland. He exhibited sphygmographic charts showing the marked increase in blood pressure following the administration of this active principle, and also the less marked increase following the administration of the aqueous extract.

DISCUSSION.

Dr. William Osler asked Dr. Abel whether he had examined any of the commercial extract of the suprarenal capsule now on the market with reference to their blood-raising properties. He had several cases of Addison's disease which he had been treating with a commercial extract of the suprarenal gland, but so far without effect.

Dr. Abel replied that he had not examined any of them, but he thought it very likely that they did contain this blood-raising principle. It was only necessary to chop up the gland and powder it.

ON THE OCCURRENCE OF THE FAT-SPLITTING FERMENT IN PERITONEAL FAT NECROSES.

A paper with this title was read by **Dr. Simon Flexner** of Baltimore.

He said that upon the etiology of peritoneal fat necrosis much light has recently been shed, partly through the findings in cases occurring in human beings and partly through animal experimentation. A study of the cases in the literature would make it appear that the occurrence of fat necrosis was not always due to the same cause. Although infection seems in certain cases to play a part, it is probable that it is not by any means the most important factor. The view has gained ground that the disseminated forms of necrosis met with in the peritoneal cavity, as well as the more circumscribed lesions in the pancreas itself, may result from a perversion of the pancreatic secretion. Again, since it has been shown that trypsin, when injected into the peritoneal cavity, does not set up this condition, the suggestion that the fat-splitting constituent of the secretion, steapsin, might possibly prove to be the chief cause, has been ventured. In the literature no record occurs of any attempt to demonstrate the presence of this body in the areas of necrosis, and it is possible that investigators were deterred by the belief in its extreme sensitiveness.

DISCUSSION.

Dr. W. H. Welch said that some years ago he had brought before the Association a case of necrosis of the pancreas in which a micro-organism was present. This was the first time on record that the colon bacillus had been demonstrated in the pancreas. Cultures were made of the colon bacillus, and presented to the Association, and he had remarked that this organism had nothing to do with the fat necrosis.

A report on "Further Studies upon the Pathogenic Spirilla of the Schuylkill River at Philadelphia" was made by **Drs. A. C. Abbot** and **D. H. Bergey** of Philadelphia.

This paper was a continuation of one read by Dr. Abbot at the last meeting of the Association, and was a record of the progress made in the demonstration of pathogenic spirilla in the drinking water of Philadelphia. A spirillum had been found resembling the spirillum of cholera in most particulars, but differing from it in a few points.

DISCUSSION.

Dr. George M. Sternberg said he considered the discovery of this spirillum in the water of the Schuylkill, at a time when there was no cholera in the country, and had not been for years, one of great importance. If the discovery had been made at a time when cholera prevailed here, this would undoubtedly have been considered the bacillus of that disease.

ON THE APPEARANCE OF CERTAIN AMEBA-LIKE BODIES IN THE BLOOD OF VACCINATED MONKEYS (RHŒSUS) AND CHILDREN, AND IN THE BLOOD OF VARIOLA. AN EXPERIMENTAL STUDY.

A paper on this subject was read by DR. WALTER REED of Washington.

Following the introduction of Koch's improved methods, the search for the specific causative agent of vaccinia had been made especially along the line of bacteriologic research. Notwithstanding many claims of positive results, these had in the end proved groundless. During the past ten years, and more especially during the last half decade, the attention of investigators had been turned toward the possibility of the animal nature of the parasite. Van Der Lœff, L. Pfeiffer, Rieck, and more recently Ogata, had described minute bodies always present in vaccine and variolous lymph, which they assign to the sporozoa. The first attempt to cultivate the supposed parasite of vaccine lymph was made in 1892 by Guarnieri, who used the cornea of guinea pigs and rabbits for this purpose. After forty-eight hours, epithelial scrapings trom the inoculated cornea, suspended in a hanging drop of aqueous humor, showed little shining slowly ameboid bodies, often with irregular margins, within the epithelial cells. Guarnieri considered these bodies to belong to the Protozoa, and called the parasite citoryctes vaccinæ.

Dr. Read's own experiments confirmed in some respects Pfeiffer's observations. Bodies of a corresponding size and ameboid in character appear in the blood of vaccinated monkeys about the 7th and disappear about the 12th day. The same bodies are found in the blood of vaccinated negro children, but were much more differcult to find in the blood of white children, and in several cases of the latter could not be discovered. Bodies of a like nature, though differing somewhat, were found in the blood of three (3) small-pox patients during the height of fever, disappearing later.

AN EPIDEMIC OF CEREBROSPINAL MENINGITIS CAUSED BY THE DIPLOCOCCUS INTRACELLULARIS MENINGITIDIS (JÆGER).

(*a*) Clinical Report; by DR. F. H. WILLIAMS of Boston.

(*b*) Pathological Report, by DR. WM. T. COUNCILMAN of Boston.

This joint paper described from both clinical and pathologic standpoints an epidemic of cerebrospinal meningitis occurring in the Boston City Hospital, and in which the diplococcus intracellularis meningitidis had been shown to be the cause. An account of the experiments undertaken with a culture of this bacillus was also given.

DISCUSSION.

DR. GUITERAS said he had two cases of the disease to report, but he regretted that he could not give the details as yet. One had occurred within the past fifteen days in the University Hospital, Philadelphia, the patient being a nurse in the hospital. He hoped to publish the details shortly. The second case occurred a few days days ago in a new-born infant, and so seemed to contradict one of the statements of Dr. Councilman.

DR. F. H. WILLIAMS said that the lumbar puncture was valuable, chiefly as a means of diagnosis. Moreover, it did sometimes give relief, but only temporarily.

DR. GEORGE M. STERNBERG asked whether any of the cases had recovered.

DR. WILLIAMS replied that seventy per cent. died.

DR. COUNCILMAN said that an interesting feature in regard to the character of the exudation, which he had meant to bring out, was that it had a marked tendency to extend along the cranial nerve, and along the optic nerve almost to the eye. The auditory nerve was also followed into the foramen. In consequence of these complications there had been loss of sight and hearing in some of the patients who recovered.

DR. F. C. SHATTUCK said that his experience with this epidemic embraced fifteen cases. A peculiar thing in his cases was that not a child died and not an adult recovered.

A CASE OF LEVANT FEVER

was reported by DR. A. A. SMITH of New York.

He gave the details of a case contracted upon the Mediterranean and treated by him in New York. The fever lasted three or four weeks, then came a period of freedom from fever, and then a period of relapse. The fever, while resembling malaria in many particulars, differed from it in that it resisted quinin in doses of twenty to ninety grains a day, whether given by the mouth or hypodermically. Anemia was not marked. The time cycle of levant fever differs from that of any form of malarial fever, being shorter than the tertian, which completes the cycle every forty-eight hours. The parasite of levant fever is larger than that of malarial fever. The only form of malarial fever with which it can be confused is the estivo-autumnal variety.

DISCUSSION.

DR. F. C. SHATTUCK asked whether arsenic had been tried.

DR. SMITH replied that every form of antimalarial medicine had been resorted to except phenic acid.

DR. GEORGE DOCK said that the diagram of the blood-cells which had been shown resembled those of malarial fever without pigment, though many observers were skeptical of the existence of such forms.

A paper on

THE EARLIEST POSSIBLE RECOGNITION OF TUBERCULOSIS,

was read by DR. JAS. T. WHITTAKER of Cincinnati.

It discussed the treatment of tuberculosis by tuberculin. Tuberculin had been objected to on the ground that its use in man had given the reaction when there were no symptoms of tuberculosis, but these should be regarded as cases of concealed tuberculosis. In lupus, actinomycosis, and allied diseases, tuberculin has produced cures. Doses of from one to ten milligrams were especially useful for their diagnostic effect. The author had never seen untoward symptoms follow the administration of even very large doses. As much as one gram had been given at a single dose in actinomycosis without producing bad effects. He had used it in 1000 cases and had never seen unpleasant symptoms follow. He believed that early cases of tuberculosis are amenable to cure by Koch's improved tuberculin.

DISCUSSION.

DR. F. C. SHATTUCK said that tuberculin was being used in the Massachusetts General Hospital for its diagnostic effects. So far as his experience goes it seems to be innocuous. Cases have been found to react to tuberculin when there were no evidences of tuberculosis, and it has been difficult to account for such cases. As an example he cited the case of a girl of twenty years who had an epigastric tumor, and it seemed improbable that it could be of a malignant nature. She reacted to tuberculin, which led to the suspicion that the tumor might be tuberculous. Later she died, and the autopsy showed that she had a sarcoma. She had, however, a tubercular nodule at the apex of the right lung.

DR. A. LAWRENCE MASON said that tuberculin had been used at the Boston City Hospital for its diagnostic properties for some years. He thought it especially valuable as an aid to diagnosis in cases of suspected tuberculous peritonitis, and as a guide to the necessity of doing laparotomies in such cases.

SOME PRODUCTS OF THE TUBERCULOSIS BACILLUS AND THE TREATMENT OF EXPERIMENTAL TUBERCULOSIS BY ANTITOXIC SERUM,

was the title of a paper by **DR. E. A. DE SCHWEINITZ** of Washington.

A description was first given of two of the products obtained from tuberculosis cultures, one of these a crystallizable acid, and its probable bearing upon the progress of the disease. A brief sketch of some experiments showing the relationship of the attenuated tuberculosis bacillus to immunity was given, followed by a description of methods for the production of antitoxic serum and its experimental application.

A paper, entitled

A FURTHER STUDY OF SOME OF THE UNTOWARD EFFECTS OF THE BROMIDS,

was read by **DR. H. A. HARE** of Philadelphia.

The author prefaced his paper with the statement that he had been led to an investigation of this subject by the remarks of Dr. S. Weir Mitchell at the last meeting of the Association. He had thought that those remarks were based upon original observations, but he had learned from correspondence with the superintendents of asylums that the subject was an old one with them. The paper was based largely upon the answers of asylum superintendents to a circular letter, and a summary showed most of them were of the belief that the administration of the bromids led to alienation and delusions. Many of them reported that the nervous symptoms ceased when the drug was discontinued. It was not the opinion that the bromids produced insanity or epilepsy, but that when given in such cases it led to the development of suicidal or homicidal mania.

DISCUSSION.

DR. H. C. WOOD said that maniacal delirium is quite common after the administration of the bromids and that it is peculiarly common in the case of epileptics. Persons subject to epilepsy are very apt to suffer from maniacal nerve storms, in which they develop suicidal or homicidal tendencies after the administration of the bromids.

DR. I. E. ATKINSON was of the opinion that the conclusions of the asylum superintendents, cited by Dr. Hare, rested upon incorrect reasoning, and thought that the attacks of mania spoken of are merely the manifestations of the epilepsy in a different form, and not the result of the bromids. Another point which he wished to make was that bromid of ammonia is far superior to the bromid of potassium or soda.

DR. HARE, in conclusion, said that nearly every asylum superintendent who had written to him ended his letter by expressing the hope that he would succeed in impressing upon the general practitioner a realization of the dangerous nature of the bromids. The first thing done when a patient enters an asylum is to get him over the effects of the bromids which have been given to quiet him. The effort is always to build up the system and cut off the bromids entirely. He did not think that these untoward effects are due especially to the bromid of potassium, but that the general depressing effect of the bromin on the general health tends to an increased mental unbalance.

The following papers were read by title :

THE EFFECTS OF VARIOUS METALS AND METALLIC SALTS ON THE GROWTH OF CERTAIN BACTERIA ;

a continuation of a similar paper read before the Association of American Physicians, May 30, 1894. By **DRS. B. MEADE BOLTON** and **W. G. BROWN** of Columbia, Mo.

A CASE OF ADENOMA ON THE LIVER WITH COMPLICATIONS,

by **DR. A. JACOBI** of New York.

THE TREATMENT OF LITHEMIA,

by **DR. B. L. RACHFORD** of Cincinnati.

PRIMARY TUBERCULOSIS OF THE KIDNEY,

by **DR. D. D. STEWART** of Philadelphia.

The following officers were elected : President, F. W. Shattuck ; Vice-President, G. Baumgarten ; Recorder, I. Minis Hays ; Secretary, Henry Hun ; Treasurer, W. W. Johnston ; Member of Council, M. A. Starr.

The following honorary members were elected : Samuel C. Chew, and F. T. Miles, Baltimore.

The following active members were elected : Arthur C. Cushney, Ann Arbor ; W. S. Thayer, Baltimore ; Ludwig Hektoen, Chicago.

AMERICAN SURGICAL ASSOCIATION.

Eighteenth Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

THIRD DAY—MAY 6TH.

(Continued from page 614.)

DR. W. W. KEEN, in discussing Dr. Tiffany's paper on "Intracranial Surgery," said that he considered disinfection in these cases of great importance. He referred to the fact that he had observed abroad in certain places that no disinfection was performed until the moment of operation, and spoke rather unfavorably of this practice. He stated that the size of the opening in the skull depends largely upon what it is necessary to do, and recommended Pyle's chisels as being the best instruments with which to make the opening. According to his experience, there were a number of objections to the use of the dental engine, but when used he considered Cryer's the best. Referring to osteoplastic operations, he stated that he had replaced the bone in probably fifteen different places, some of them being as large as 1½ inches in diameter, without any bad results, but advised that these replacements be done with the utmost care. He always keeps the pieces of bone that have been removed in a 1 to 2000 solution of bichlorid of mercury at a temperature of from 100° to 150° F., placing therein a thermometer and detailing one nurse to exclusively attend to it. If the pieces of bone are not replaced, the membrane will fill up the aperture and leave a depression which in the case of the forehead is quite objectionable.

He favored performing these operations in two stages, at a interval of from one to two months, under ordinary circumstances, although in some cases not more than three or four days should be allowed to elapse. In his opinion the greatest danger in re-opening a wound is the risk of infection. The two principal factors in cerebral surgery are the time that elapses during the opening of the skull and the hemorrhage, and he referred to a recent case in which almost every possible means of controlling hemorrhage failed until it was feared the patient would die on the table. A previous operation was performed on the same patient, and also a subsequent one without this alarming symptom presenting itself.

Dr. Robert Weir of New York also referred to the question of hemorrhage, and stated that he employs one or two moderate-sized hat pins over which he places two or three stout rubber bands, and these, with the occasional use of the clamp, and sometimes of a band around the head, usually control it. To a large extent he has given up the use of the chisel in these operations, and especially in the cases of a thick skull. He rarely resorts to osteoplastic operation at the present time, and prefers to allow for intracranal pressure. Of late years he has preferred the electric saw for these operations. In closing these wounds he stated that he is in the habit of using a celluloid plate and reported a case in which good results have been maintained for five years.

Dr. J. Parmenter of Buffalo preferred the gouge and hammer to the chisel for opening the skull, and believed that the dangers are less. Speaking of the surgical engine and the electric saw, he did not see any objection to their use if the cranial bones are vascular, but if they are not, necrosis will follow. As to controlling hemorrhage, he prefers a modification of Dr. Weir's method, and considers the forceps the best instrument for crushing bone. He thought the practice of palpating the intracranial structures a bad one, as it is attended by much risk. He considers cleanliness in these cases of vital importance, and referred to a case in which he recently opened a previously closed wound and found glass and other substances imbedded. Excellent results followed the complete cleansing of this wound.

Dr. S. J. Mixter of Boston believed in the employment of extensive flaps in these operations, instead of running the risk of having to enlarge the incision afterward. He considered the trephin the most used instrument for opening the skull, and recommended that it should never be over three-quarters of an inch in diameter. He thought it might be well, when dividing the operation into two stages, to place between the skull and the skin a piece of celluloid to prevent adhesion. He advised pressure as the best means of controlling hemorrhage, and considered that an important question to be decided was the amount of pressure the brain can stand, he believing that it is sometime doubtful in fatal cases whether death is due to hemorrhage or to compression. Again, in cases of hernia of the brain, the question of the amount of pressure to be employed is important. He strongly recommended that a skilled pathologist should be present where an exploration of the brain is to be made to determine the presence of a tumor so that small fragments removed may be immediately examined and their nature determined. He thought that the question of closing the wound or leaving it open is still unsettled.

Dr. Christian Fenger of Chicago read a paper, entitled

URETERECTOMY.

He treated the subject under three headings: First, when the ureter is removed simultaneously with the kidney; second, when, after nephrectomy, the removal of the ureter of the same side becomes necessary; and third, when the entire ureter is removed alone. He also referred to a partial operation when only a portion of the ureter is taken away. He divided the operation into four kinds: First, transperitoneal; second, extraperitoneal; third, sacral; and fourth, transvaginal. He stated that ureterectomy has been performed for tuberculosis, suppuration in the dilated ureter, hydrops of the ureter, and for non-infected dilated ureter. He said that primary total ureterectomy was performed by Kelly, in 1896; primary partial ureterectomy by Tuffier, in 1891, by Kelly, in 1893, and by Postnikow, in 1892. Secondary total ureterectomy was performed by Reynier, in 1892, and secondary partial ureterectomy by Poncet, in 1894. He concluded his paper by giving a number of statistics of the various operations.

Dr. A. T. Cabot of Boston considered the ureter as being very accessible extraperitoneally by the Isarel incision. In removing a portion of the ureter he thought the question of the advisability of removing the last few inches must be settled at the time of the operation. He saw no especial advantage in transplanting the end of the ureter into the vagina, and thought the discharge from a lumbar fistula quite as endurable as a discharge from the vagina. He did not think the operation of ureterectomy is called for, except when extensive suppuration or whe tuberculosis exists. He advised cutting off the ureter a low as possible when tuberculosis exists, and stated tha the remainder could be removed at a subsequent operatio if necessary.

Dr. M. H. Richardson of Boston showed some colored pictures of a case of extirpated ureter.

A CASE OF FEUGER'S PYELOPLASTY FOR INTERMITTENT HYDRONEPHROSIS

was reported by Dr. Maurice H. Richardson of Boston.

A woman of twenty-nine presented a tumor of varying size in the region of the gall-bladder. The tumor could be felt only when there was pain and tenderness in the side. It was supposed to be a distended gall-bladder, and was exposed March 17, 1896. It proved to be an enlarged renal pelvis. With the subsidence of the tumor there was an increase in the amount of urine. After recovery from the exploration the patient had a recurrence of the distress and pain, with reappearance of the tumor. On October 22, 1896 the speaker did the operation upon the kidney, described and performed by Feuger. The operation may have differed in some details, but the principle was Feuger's, as described in the *Annals of Surgery*. The pelvis of the right kidney was enormously enlarged. The ureter was inserted obliquely into the dilated pelvis. The distended pelvis pressed upon the spur sufficiently to obstruct the urinary flow. After free exposure of the parts by extensive lateral abdominal incision, the outer wall of the ureter and the contiguous inner surface of the pelvis were incised as described by Feuger. This longitudinal incision was converted into a transverse one by means of fine silk, as in the Heincke-Miculicz pyeloplastic operation. The exit of urine could then take place through a funnel-shaped opening. The patient made a perfect recovery. She was exhibited in April, 1897, at the Clinical Society of the Manhattan General Hospital. There had been no recurrence of the symptoms; no tumor could be felt.

Dr. Richardson also reported a case of "Chronic Intestinal Obstruction from Incomplete Volvulus of the Sigmoid Flexure."

HABITUAL DISLOCATION OF THE SHOULDER-JOINT

was the title of a paper by Drs. Herbert L. Burrell and R. W. Lovett of Boston.

The authors said that the term "habitual dislocation" should be restricted to cases where secondary dislocations occur from insufficient cause. Such cases show an atrophy of certain muscles. These are the scapula muscles, the latissimus dorsi, the triceps, the deltoid, and the coracobrachialis. There is no reaction of degeneration n these muscles. The fluoroscope shows that the X-ray penetrates the affected side more slowly than the other, and it can be seen that the head of the humerus on the affected side is further from the acromion. Pathologic evidence shows that there may be abnormality of the head f the humerus, rupture, and displacement of tendons and ntra-articular fracture. Laxity of the joint capsule is almost universally noted.

The prognosis is that continued dislocations, increasing n frequency, will result if no treatment is undertaken.

The treatment may be (1) by apparatus (which is condemned), (2) by massage, (3) by massage and prolonged xation, (4) by operation.

(*a*) Excision has been done in the past, but is mutilating, and has been superseded to a great extent by a simpler operation. (*b*) An anterior incision exposing the joint should be made, and after exploration of the joint, an elliptical piece of the joint capsule should be excised, and the capsule sewed up.

Two cases successfully operated on by this method by Dr. Burrell were reported.

Many other papers were read by title.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-third Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

First Day—May 4th.

Dr. M. Allen Starr of New York delivered the presidential address on

THE TRANSMISSION OF SENSORY IMPULSES THROUGH THE SPINAL CORD.

He thought that the conclusions derived from physiologic experiments upon the lower animals were open to grave criticism, first, because of the fact that the majority of such experiments performed years ago were carried out without antiseptic precautions, and were attended by secondary septic inflammations of the cord and its meninges, which invalidated the conclusions drawn from them; and, secondly, because of the great variation in the anatomic structure of the cords of the lower animals and of man.

It is no longer possible to speak of the columns of the cord as being exclusively ascending or descending in the direction of their fiber. Recent investigations by Hoche showed the existence of many association fibers of limited extent in the direct cerebellar columns and in the columns of Gowers, and therefore it seemed evident that every column of the cord contained fibers which passed in both directions.

Is it not evident, therefore, in the transmission of sensation through the spinal cord, cerebral axis and brain that we have to consider the tracts as different in their structure from those conveying motor impulses, and as consisting of a series of short neurons closely connected but with very numerous and widespread connections? Is it not probable that the result of this arrangement is to secure a diffusion of single sensations to various reflex, vasomotor, trophic, and automatic mechanisms as well as to the organ of conscious perception? And is it not also evident that this view of sensory diffusion explains the apparent inconsistency, at present prevailing between the clinical symptoms observed in Brown-Séquard paralysis, and the pathologic degenerations occurring in that disease?

Dr. Morton Prince of Boston reported three cases of "primary idiopathic hydrocephalus" in adults with autopsies, besides two others which terminated in recovery. The first case followed trauma and simulated latent abscess with secondary meningitis of the base. Trephining was done with negative result. At the autopsy the venticles were found dilated to three times their normal size, the convolutions flattened, and the sulci almost obliterated. The speaker said that there is an acute and a chronic form of the condition. The acute simulates the purulent form of meningitis, but differs from it in its course and the variability of the symptoms. The chronic simulates and is usually mistaken for cerebral tumor. The affection is common but not usually recognized.

AUDITORY APHASIA

was the title of a paper by DR. HOWELL T. PERSHING of Denver.

He said that auditory aphasia is the sum total of speech defects due to a lesion of the auditory center for words; it is a more precise term than sensory aphasia, and more comprehensive than word-deafness. The reader reported, as typical of auditory aphasia, a case in which the symptoms were word-deafness, verbal amnesia, jargon paraphasia, paralexia, loss of comprehension of print, and agraphia, with retention of ability to copy Roman letters into script, and with no visual defects.

DR. PHILIP ZENNER of Cincinnati referred to a case with frequent attacks of word-deafness and spasm of the right side of the tongue and face. At the autopsy a tumor was found in the lower part of the Rolandic fissure, resting upon the first temporal convolution.

DR. G. L. WALTON of Boston read a paper, entitled

SUBARACHNOID SEROUS EXUDATION PRODUCTIVE OF PRESSURE-SYMPTOMS AFTER HEAD INJURIES.

The author arrived at the following conclusions: (1) A severe blow may result in local bruising and congestion with subarachnoid serous exudation. (2) The fluid may be imprisoned and cause focal paralysis. (3) The process is not compensatory, and is allied to the serous meningitis of Quincki. (4) The lesion is self-limiting. (5) Diagnosis from hemorrhage is difficult; atypical course. Absence of steady increase of symptoms, and persistence of sensitiveness point toward serous exudation. (6) Immediate operation is not necessarily indicated in focal paralysis, though perhaps always justifiable. (7) This condition is specially to be borne in mind before operating on children and young adults.

DR. B. SACHS of New York said the theory was not new. After head injuries, three possibilities were to be considered —hemorrhage, local edema, and purulent meningitis. The view of Dr. Walton was natural and plausible, and he agreed with him as to differential diagnosis. He would not operate on the skull too soon, not until after the lapse of forty-eight hours or several days.

DR. J. J. PUTNAM of Boston had seen several cases in which such a diagnosis could be borne out, but there was shifting of symptoms, which was important.

DR. C. A. HERTER of New York believed that local effusion could give rise to these symptoms, and spoke of a case of extreme general edema of the arachnoid following syphilis.

DR. JOSEPH COLLINS of New York related the case of a man, fifty years of age, who fell and struck his head in the left parietal region. This was followed by shock, stupor, and paralysis of the right upper extremity. At the autopsy there was some localized serous exudation, which was evidently of inflammatory origin.

DR. J. J. PUTNAM had seen venous hemorrhage into the pia, which was accompanied by hemiplagia.

The PRESIDENT thought that the question of localized edema should be one of fact and not of theory. He had seen three cases operated upon in which apparent inflammatory edema was found. He had also observed a case in which there was a very large amount of edema involving the entire hemisphere around a very small tumor.

ANESTHESIA IN DISEASES OF THE SPINAL CORD.

This paper was read by DR. PHILIP COOMBES KNAPP of Boston. He referred to the researches of Ross, Thorburn, Starr, and others. In syringomyelia the distribution of the anesthesia is more apt to follow another type, as in cerebral disease, where the boundary of the anesthesia is at right angles to the axis of the limb. Two cases were reported and many others cited proving this distribution. In other cases, however, as shown by by Lachr, the sensory disturbances are of the spinal type. Brissaud endeavored to explain this difference by referring the cases with anesthesia of the spinal type to root lesions, and those with anesthesia of the cerebral type to lesions of the central gray matter of the cord; and Chipault, accepting that hypothesis, found that in the paraplegia of spinal caries both types occur, which he thought a valuable distinction between lesions of the roots and lesions involving the cord itself.

DR. B. SACHS referred to cases of spinal origin, which, however, do not seem to be of spinal type, but which he had good reason to believe presented a syphilitic affection of the cervical region of the cord. This type closely resembled syringomyelia. He did not like the term "cerebral anesthesia," but preferred "regional anesthesia."

The PRESIDENT said that it is practically impossible to lay down an accurate diagram of the anesthesias from various regions of the cord. Individual variations must be considered and admitted. Irregularity in distribution is characteristic of spinal anesthesia.

DR. FRANK R. FRY of St. Louis reported a case of

SPINAL LEPTOMENINGITIS.

A bacteriologic examination showed the infection to be purely purulent. The scource of infection was a slight but rather chronic furunculosis on the back of the neck—the patient was a male house servant 27 years of age. The site of primary infection was the lumbar or lower dorsal region. The clinical history was that of an ascending paralysis with certain interesting features of temperature, etc. There was no cerebral involvement.

DR. HUGH T. PATRICK of Chicago reported

A CASE OF SYRINGOMYELIA.

A man of forty-four years began to be weak in the legs ten years ago, which weakness gradually increased until he walked with difficulty. A year ago the hands also began to be affected. Examination showed spastic paraplegia with weakness of the grasp and slight atrophy of the small hand muscles. The sensory symptoms were most interesting. There was a band of anesthesia about the trunk and extending on to the inner surface of the arms; an area of analgesia covered this and extended beyond it about four inches on the trunk and two inches on the arms. This distribution of sensory blunting is exactly the same as that which has been described by Laehr and the author as occurring in tabes, except that in the latter disease the band of analgesia is much narrower than that of anesthesia.

SECOND DAY—MAY 5TH.

ENCEPHALITIS WITH CHANGES IN THE PIA.

Dr. Alfred Wiener of New York read a paper on this subject and reported the case of a child three years of age, who, after meeting with an accident suffered from an attack of acute (non-suppurative) meningo-encephalitis. The child recovered after six months of illness. It reremained perfectly well, and after an interval of three years, just subsequent to an attendance of three months at school, had a second attack which proved fatal. The autopsy and microscopic examination showed an involvement of the pia as well as the brain and the characteristic picture of acute non-suppurative hemorrhagic encephalitis.

LITTLE'S DISEASE. SHALL WE RETAIN THE NAME?

This was the title of a paper read by **Dr. B. Sachs** of New York. He said that the use of the term "Little's disease" has led to great confusion. German and French authors have criticised English and American writers for not recognizing the disease as a distinct clinical entity. The name has not been adopted by the latter for the simple reason that Little's disease cannot be considered as anything more than a mere etiologic group comprising those cases of early infantile spastic palsies which are due to difficulties during labor resulting in asphyxia neonatorem. It cannot even comprise all spastic palsies that are in evidence from the time of birth, for many of them are not due to asphyxia, but to developmental defects, more particularly of the cortical or corticospinal division of the pyramidal tract. Some authors would make a distinction between general rigidity and cerebral diplegias and would call the cases of the former, Little's disease, but he is of the opinion that there is no rigidity without paralysis, and the difference is simply one of degree and not of kind. The division which the reader made into prenatal and birth palsies which has been endorsed by Freud should be continued, and the name Little's disease should be dismissed since it represents no distinct clinical group, and since a number of different morbid conditions are responsible for the infantile spastic palsies, or the cases of general rigidity appearing at the time of birth or shortly thereafter.

Dr. Frederick Peterson of New York differed from Dr. Sachs, as he had found that the greater the extent of the paralysis, the more the mental defect and epilepsy. At times he had found extensive paralysis without mental defect or epilepsy. He referred to 130 cases as having been reported, in which there were 30 with hemorrhage into the spinal canal.

Dr. J. W. Putnam of Buffalo said that cases varied in the symptoms according to their etiology. He spoke of two children in one family in whom there was extensive paralysis. One had marked mental defect and the other very little. Both pregnancies were attended with prolonged periods of vomiting.

THE NATURE AND TREATMENT OF SPASMODIC TORTICOLLIS.

Dr. G. L. Walton of Boston read this paper. He considered spasmodic torticollis as an affection of the cortical centers for rotation of the head. The pathology is not settled. The fact that it is sometimes easily inhibited does not establish a mental origin. Gross organic lesion is not present. Long-continued habit may merge into spasm, as seen in certain occupations. Eye-strain sometimes plays a part, through causing faulty position (oblique astigmatism, muscular insufficiencies). In one case it followed the wearing of a glass which increased instead of relieving an oblique astigmatism. The course of the disease is progressive. The principal muscles affected are the sternomastoid, splenius capitis, complexus, trachelomastoid, and the inferior oblique. The commonest form implicates the sternomastoid of one side and the posterior rotators of the other; less frequently the spasm is limited to the sternomastoid, occasionally to the posterior rotators of both sides (retrocollis), and rarely to the sternomastoid and posterior rotators of the same side. Treatment other than operative is ineffectual in well-established cases. Simple nerve-stretching is unavailing. The only operations to be considered are resection of nerves and section of muscles. Operations are generally too limited rather than too extensive. In most cases it will be necessary to resect the spinal accessory and the first three posterior branches of the cervical nerves. It will generally be wise to cut, also, the affected muscles. Muscle section alone has given good results (Kocher), but there is no reason to abandon nerve resection.

Absolute cure cannot be expected in over half the cases, improvement in a greater proportion, and failure in a certain proportion.

Dr. W. M. Leszynsky of New York, after briefly referring to his successful use of increasing doses of atropin injected into the spasmodic muscles, mentioned the case of a lady thirty-five years of age, who had been under constant observation for the last eighteen months. The clonic spasm had previously existed for six months, and involved the sternomastoid, trapezius, and complexus. The sternomastoid was hypertrophied to about four times its natural size. Atropin treatment could not be carried out, owing to idiosyncrasy. Conium and gelsemium failed. After prolonged rest and tonic treatment, together with local massage, passive movements, and educational gymnastics faithfully carried out, the clonic spasm was absolutely cured, having been absent for nearly ten months. This has, however, been replaced by a mild form of tonic spasm, which is remittent. A peculiar feature in the case was the high specific gravity of the urine, which was due to urates. Whenever the gravity rose to 1030 to 1034, the spasm increased, seemingly indicating an autotoxic irritative element in the case. He believed that if these cases were treated early by the foregoing method, very little would be left for the surgeon.

THIRD DAY—MAY 6TH.

AN UNCOMMON NASAL PARAESTHETIC NEUROSIS.

This was the title of a paper read by DR. SAMUEL AYRES of Pittsburg, who reported the case of a lady twenty-three years of age, recently married and of a neurotic temperament. The nasal disturbance began eight years ago, and was characterized by periodic flushings over the end of the nose. The attacks have increased in frequency and now consist in a sense of burning in the integument of the end of the nose, or over the entire cartilaginous portion. At the same time, there is general restlessness and considerable mental depression. No cause could be discovered. Various remedies had been used, such as local applications and the internal administration of bromids, cannabis indica, ergotin, etc., with only temporary benefit.

STEPS TOWARD INSANITY.

DR. SMITH BAKER of Utica read this paper, and said that the biologic doctrine that structure determines function is as applicable to the neuron as to other basal elements. Applied to insanity, psychiatry properly becomes an important branch of it. The primary presupposition of every instance of true insanity is that it is based upon arrest of development and a nurture too faulty to correct it. The step which initiates the degenerative tendency is unphysiologic marriage, and the perversive tensions and reactions which grow out of them. Another step is where two healthy people vitiate themselves by over-stress or nutritional perversions during the child-bearing period. With the individual, defective homing plays a most prominent part in fixating degenerative tendencies. Frequently the ordinary educational course, the universal leaning on proxies, and various kinds of stimulants, are but ways of confirming all that are degenerative. Diseases and accidents are important because of the emotional stress involved. Arrest of development at puberty is serious always. The immediate causation of the structural change seems to come through exhaustion and auto-intoxication. This must interfere with the characteristic activity of the neurons, which activity seems to be on the point of discovery as an ameboid movement of the cells or their processes. Dissociation, confusion, systematization may thus come to be founded in actual structural defect, itself the result, primarily, of emotional stress in ancestry.

A number of other papers were read by title.

The following were elected to membership: Dr. Wm. G. Spiller of Philadelphia, Dr. H. M. Thomas of Baltimore, and Dr. Wm. Hirsch of New York.

Dr. E. C. Seguin of New York was elected an honorary member.

The following officers were elected for the ensuing year: President, Dr. G. M. Hammond of New York; Vice-presidents, Dr. Philip Zenner of Cincinnati and Dr. J. J. Putnam of Boston; Secretary and Treasurer, Dr. F. X. Dercum of Philadelphia; Councils, Dr. H. T. Patrick of Chicago and Dr. Chas. K. Mills of Philadelphia.

AMERICAN ORTHOPEDIC ASSOCIATION.

Eleventh Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

FIRST DAY—MAY 4TH.

THE President, DR. SAMUEL KETCH of New York, opened the proceedings by delivering an address on

THE WORK AND INFLUENCE OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

He said that just ten years ago the American Orthopedic Association was born—the youngest offspring of surgery. During these ten years its members have presented 323 papers, covering every part of orthopedic surgery. Thus, 35 papers had been on hip-joint disease, 19 on knee-joint disease, 49 on Pott's disease, 20 on lateral curvature of the spine, 6 on torticollis, 14 on congenital dislocation of the hip, 43 on clubfoot, and 79 on spastic paraplegia. This should, in itself, be conclusive proof of the good scientific work that has been done, and also a refutation of the charge that orthopedic surgery is a specialty having very narrow limits. The influence that the Association has exerted was, perhaps, best shown by the fact that up to ten years ago but few of the medical schools made any attempt to teach orthopedic surgery, and only three had a systematic course. To-day, orthopedic surgery is as much a recognized branch as are the other surgical specialties. It has passed forever out of the hands of the instrument-makers, quacks, and bone-setters. Probably the day is not far distant when there will be a journal devoted exclusively to this specialty. There is every indication that the Röntgen ray will prove peculiarly useful in this branch of surgery, and that it will clear up many points now shrouded in obscurity. The address closed with memorial sketches of recently deceased members, including one of the venerable Dr. Henry G. Davis, "The father of American orthopedic surgery," and the originator of extension in the treatment of joint diseases.

DR. HARRY M. SHERMAN of San Francisco read a paper on

ERASION OF THE KNEE-JOINT WITH CONSERVATION OF THE EPIPHYSEAL CARTILAGE.

Epiphyseal ossification, the speaker said, takes place on the diaphyseal side of the cartilage. If all the diseased tissue can be removed without interfering with the cartilage, it is reasonable to suppose that a certain amount of the developmental energy of that cartilage may be conserved. The paper was based chiefly on an experience with three cases. Two of the patients presented themselves with marked flexion at the knee, with sinuses opening in front, and with the head of the tibia dislocated backward. Total arthrectomy and epiphyseotomy were performed in each case. The epiphyseal cartilages were preserved. Healing was uneventful, and each patient left the hospital with the limb straight and apparently solid. But in each case flexion occurred while the child was still under observation, and in spite of solid plaster-of-Paris splints. In one case, as shown in the radiographs presented, there had been a certain amount of growth at the knee since the operation. The radiograph also showed that the flexion was due to the development of more bone in the anterior than in the posterior cartilage. The third case had been seen in a very early stage of the disease, and at first had done very well with a Thomas walking splint, except that an area of tenderness had persisted over the inner tibial tuberosity. The tissues over this portion were slightly boggy and condensed. After about two years, the case had been operated upon, the joint being removed, with the exception of the epiphyseal cartilages. The epiphyseal cartilages sloughed away with the exception of a circumferential band. This annular band had been sufficient to maintain the growth of the limb, and was shown by the fact that the amount of shortening had not altered. The general result had been most satisfactory, the functions of the limb being practically perfect. The radiograph showed that the cavity after the operation had been filled by a bone of rather lighter structure than the other bone. Dr. Sherman said that according to Mr. Cheyne it is important to locate and remove a tuberculous focus at an early stage, as this is often the means of cutting short the disease. By exploratory puncture with a needle, carried out with proper judgment, one can readily distinguish between tuberculous bone and sound bone, even in a young child.

Dr. Charles L. Scudder of Boston said that the flexion referred to did not seem to him an undesirable complication; a slight amount of flexion—8° or 10°—was more comfortable to the patient than when the knee was absolutely straight.

Dr. R. W. Lovett of Boston said that his experience with arthrectomy had been very discouraging, but his results with excision, even when done late, and in bad cases, had been extraordinary. While he was of the opinion that our progress in the management of hip disease would be chiefly in the direction of earlier excision in selected cases, yet his personal experience with the conservative treatment of early cases of hip disease had been quite satisfactory, and he was rather opposed to operative treatment in cases of knee-joint disease.

The President said that all surgeons had noted after excision that flexion was prone to occur, sometimes to a degree almost equal to the original deformity. Personally, he had found the conservative treatment of knee-joint disease in children favorable.

Dr. Sherman, in closing the discussion, referred to the question of focal operations at an early stage. He said that Mr. Cheyne went further than Mr. Barker and Mr. Wright, in that he advocated operating upon a lesion as soon as it could be definitely located by the swelling and tenderness. In children, Dr. Sherman thought, it is difficult to locate such a focus by tenderness, but the thickening of the tissues might lead one to suspect the presence of such a focus. Mr. Cheyne's suggestion might be applicable to all joints except the hip. The latter should be excluded, owing to its deep situation and the absolute inability of the operator to know whether or not he has removed all diseased tissue. As we know the ordinary locations of the early foci of disease, we can usually do an exploratory operation with a small trephine.

CASES OF TRAUMATIC SPONDYLITIS.

Dr. Arthur J. Gillette of St. Paul reported some cases of this kind. In the first one, the patient had slipped slightly on the sidewalk, following which there was paraplegia. After this had existed for five months, Dr. Gillette had first seen him, and had found a slight prominence in the upper dorsal region. This was associated with some rigidity and pain. The temperature range was quite typical of tuberculosis. Extension did not give relief as usual. The *post-mortem* examination showed the vertebral column, from the upper dorsal vertebræ to the sacrum, to be soft and spongy. The vertebræ throughout the column could be easily crushed with the fingers. The crest of the ilium, the ribs and the sternum were in the same condition. There was extensive tubercular disease of the lung, and enlargement of the liver and spleen.

The second case was that of a young farmer, of perfect development. He had severely sprained his back a few months before coming under observation. There was no immediate involvement of the spinal cord, but when first seen by the speaker, he was unable to walk, and there were exaggerated knee reflexes and marked ankle clonus. Any sudden jar caused pain in the back and legs. There was a slight prominence in the lower dorsal spine, and the muscles were rigid along the spinal column. While partially suspended for the application of a jacket, the patient had a severe attack of syncope. The case then developed the symptoms of basilar meningitis, and later on those of pleuritic effusion. Examination of the spinal column, *post-mortem*, was all that was allowed. The spinal cord was intact, and the membranes softened. In the upper dorsal region was a sinus passing into the left pleural cavity. This cavity contained apparently the same kind of fluid as the vertebral canal. Both the anterior and posterior segments of the vertebræ were carious.

The third case was in a robust young woodman, who sprained his back, and then developed symptoms and signs apparently indicative of vertebral caries. There were no symptoms of spinal-cord involvement. After a considerable time the patient died, and the *post-mortem* showed marked degeneration of the kidneys, a fatty liver, and a pulpy, dark red spleen weighing three pounds and four ounces. The was no evidence of tuberculosis in the lungs or spinal column. The spongy portion of several of the vertebræ had been reduced to a dark, pulpy mass.

Dr. R. W. Lovett presented a case of what he supposed to be

SPONDYLOLISTHESIS.

The patient was a youth of eighteen years, seen last September. He was of good physique, and enjoyed good health previously. In April, 1896, a wagon weighing 2600 pounds had passed over his pelvis. There had been no discharge of blood from the urethra or rectum after the accident, and after remaining in bed for a week or two without medical treatment, he began going around on crutches. When first seen by the speaker he walked in a bent attitude, leaning to the right. Movement in all directions was painful. The knee reflexes and the aspect of the case was that of a severe case of lumbar disease with abscess. The shape of the hips, however, was almost like that of congenital dislocation of the hips, except that the trochanters were on Nelaton's line. They seemed, nevertheless, unduly prominent. The lumbar spine appeared to project forward abnormally, while the sacrum was in normal position. A plaster jacket was applied under suspension, and it gave relief. In February, 1897, he was so much better that a laced jacket was substituted. A few days age, the man was discharged from treatment as all symptoms had disappeared. The deformity of the lumbar spine persisted, but it was apparently less marked than before. No motions were painful. The patient was no longer conscious of any disability.

DR. LOVETT said that the literature of spondylolisthesis was quite meagre. According to Neugebauer there are about ninety cases on record. It is probably due to a congenital deformity; or a defect of development, owing to atrophy produced by pressure.

THE PRESIDENT referred to the case of a young woman who had had a well-marked protrusion of the dorsal spine, with complete paraplegia of the lower extremities, and, for a time, of the arms. The girl had come to him originally as a case of round shoulders. The paraplegia developed about six months after treatment had been begun with an anteroposterior apparatus. After having been on a water-bed for two years, she died of exhaustion. The *post-mortem* examination was made by Dr. T. Halsted Myers, and no lesion of any kind was found in the vertebræ. The pathologist who examined the spinal cord never reported his findings. No organic lesions were found, and yet those who had seen the case during life felt convinced that it was neither a case of hysteria nor of malingering.

DR. E. G. BRACKETT of Boston presented a paper on

THE TREATMENT OF TORTICOLLIS.

He said that surgeons are pretty well agreed, (1) that the contracted structures lying superficial to the deep layer of fascia must be overcome; (2) that the deeper structures—the muscles, ligaments of the spine, and all the parts involved in holding the head—must be further stretched; and (3), that we must correct the "habit" of holding the head in an abnormal position. Habit was hardly the word to be used, but owing to a readaptation of the muscles, the head would be held in an abnormal position unless systematic effort was made to overcome it. The structural changes in the ligaments, muscles, etc., should be overcome by stretching or by massage. When the head was put up in over-correction, it was continually stretched, but, in *selected* cases, one could depend upon the intermittent traction resulting from active massage and exercises. A roll should be placed under the neck of the patient, who should lie with the head turned to the opposite side in such a way as to cause overcorrection of the deformity. In that position deep massage should be practised on the contracted structures, and on the trapezius of the opposite side. The next step was to make, up to the point of tolerance, forcible manipulations —depressing the head, etc. In the next place, the head being held as nearly in the correct position as possible, the patient should be required to do heavy work with dumb-bells, the muscles being made to work in their long arc instead of the short one.

In connection with this subject of the treatment of torticollis, Dr. Brackett said he desired to allude to an accident or complication which he had not seen described before. In the case of the older patient, described in the cases appended to his paper, this accident had occurred: The patient had taken the ether very well. On attempting to correct the position of the head, his color became peculiar, and the respirations suddenly became shallow. These symptoms disappeared on releasing the head, but the same alarming symptoms recurred on returning the head to the corrected position. On this account it became necessary to use only a moderate correction at the time of the operation. Three days later, on attempting to correct the position, the boy developed the same symptoms, and fainted. This was repeated at the next attempt at correction. Even at the present time, if the head were corrected beyond a certain point, there would be a partial return of these symptoms. The only explanation that had suggested itself to him was that the vagus nerve had also become short along the line of the vessels, and had been thus put on the stretch when correction had been carried beyond a certain point.

DR. LEROY W. HUBBARD of New York said that he had recently treated a case of congenital torticollis in a girl of twenty-eight years. In this case the right shoulder had been elevated two inches, the right sternocleidomastoid muscle markedly shortened, and the whole right side of the face considerably atrophied, giving to the face a very peculiar expression. On January 5, 1897, he had operated by the open incision, dividing the sternomastoid in the middle, and also the trapezius and all contracted tissues. The parts were thoroughly stretched under ether, and the head put up in plaster of Paris in an overcorrected position. After about ten days, the wound having healed, the plaster was removed, and further correction was made before reapplying the plaster of Paris. Subsequently, a spinal apparatus with a Taylor chinpiece was substituted for the plaster. This was worn for about two months, and each day the patient was subjected to manipulations similar to those described in the paper. At the present time she held the head in good position, and could move it easily in all directions. She had not worn an apparatus for about two months. There was still some elevation of the right clavicle, and also some lateral curvature of the cervical spine, which had been very marked before the operation. The stretching and massage are very important in these cases of persistent torticollis.

DR. SHAFFER thought that certain cases of torticollis could be relieved by systematic massage and intermittent traction. The great difficulty is to get the proper points for extension and counter-extension.

In one case that he had seen, instead of a unilateral contraction, both sternomastoid muscles had been contracted, producing a forward position of the head not unlike the position assumed in Pott's disease. In this case there must have been a double lesion of the nerve and muscle.

THE TUBERCULIN TEST IN INCIPIENT AND SUSPECTED PULMONARY TUBERCULOSIS.

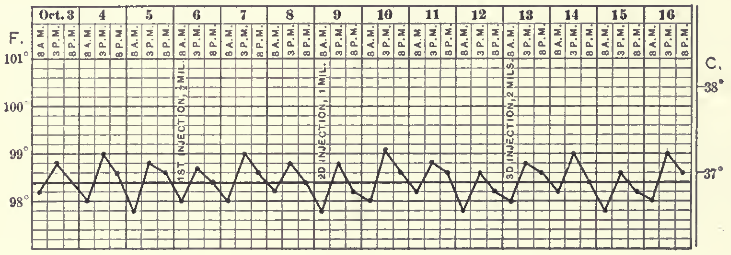
BY E. L. TRUDEAU, M.D.,
OF SARANAC LAKE, N. Y.

THE importance of making an early diagnosis in cases of tuberculosis cannot be too strongly emphasized. While studies in the autopsy-room have shown how often incipient tuberculosis is healed in man without its presence having even been suspected, clinical observation teaches daily how powerless we are to deal with the disease in its advanced stages, and how a latent pulmonary tuberculosis may be transformed into a hopeless and rapidly fatal disease when the unrecognized tuberculous process has gone on to ulceration, and when secondary infection has supervened.

The diagnosis of incipient and latent pulmonary tuberculosis, though often surrounded by many difficulties, can generally be made by a careful consideration of the history of the case, the rational symptoms, and the physical signs collectively, aided by a microscopic examination of any expectoration obtainable from the patient. Often at this stage of the disease, however, no expectoration is obtainable, or the bacillus has not yet appeared in it, and a most thorough examination of the chest and study of the symptoms fails to afford sufficient evidence to enable the examiner to reach a positive conclusion. He is therefore obliged to wait for the well-known symptoms to appear, and waiting means to jeopardize the patient's best chances of recovery. The application of the tuberculin test to such cases will often throw much needed light upon them, enabling the physician to reach a positive conclusion, and will give the patient all the chances of recovery that lie in the detection of the disease at such an early stage, before extensive lesions have developed, or secondary infection has occurred.

Besides its value in detecting latent tuberculosis, the tuberculin test may be found, in future, to have a wide range of usefulness, not only to the physician, but to the surgeon as well, in the differentiation of many morbid processes which simulate tuberculosis, and the nature of which cannot be positively ascertained. The differentiation of an inflammatory bronchitis of chronic type from pulmonary phthisis, of tuberculous pleuritis from the other forms of the affection, of an unresolved pneumonic process from a cheesy pneumonia, of simple inflammatory pyelitis and cystitis from the tuberculous variety of these diseases, and of a gonorrheal or rheumatic from a tuberculous synovitis, is often very difficult, and much light as to the exact nature of the process under observation may be expected by a careful application of the tuberculin test to such cases. In view of the demonstrated accuracy of this test when applied to cattle and to other animals artificially inoculated in the course of laboratory research, where its correctness can be controlled by autopsy, it is remarkable that a method which has proved itself so generally reliable in detecting the disease in animals, and which offered such possibilities as a diagnostic agent when applied to man, should have been so almost universally neglected and generally condemned on scant evidence as utterly worthless and dangerous. This, no doubt, has been due, in a great measure, to the bitter disappointment which followed the acclamation of tuberculin as an infallible specific, and to the unquestionable evil effects of its indiscriminate and injudicious application to the treatment of human tuberculosis. To those, however, who continued quietly the study of tuberculin, it soon became apparent that while its beneficial influence as a therapeutic agent could be exercised only within certain very restricted limits, its undoubted diagnostic value steadily became more and more evident in the light of slowly accumulating experience in its use. So general in this country has been the condemnation of the use of tuberculin for any purpose, when applied to the human being, that but little evidence in regard to its diagnostic value, except as applied to cattle, has thus far been presented.

Among European observers the opinions are somewhat divided, but tend to show that while it is not infallible, it cannot any longer be ignored as an aid to diagnosis in obscure or latent cases. Von Jaksch (*Verhand. der Congress f. Innere Med.*, 1891), after using it in twenty-eight cases, concludes that tuberculin has a high diagnostic value. Guttsdat has collected figures from German clinics which show that a well-defined reaction occurred in eight per cent. of apparently healthy individuals, in ninety-five per cent. of cases known to be tuberculous, and in twenty-seven per cent. of cases suspected of tuberculosis. Maragliano (*Berlin Klin. Woch.*, No. 19-20, 1896) obtained a reaction in nine per cent. of apparently sound individuals, and in twenty-three per cent. of patients suspected of tuberculosis, but without any well-defined symptoms. Maragliano carried his tests to doses as high as ten to twenty-five milligrams in cases which failed to react to smaller doses. Grasset and Vedel (*Semaine Médicale*, Feb. 26, 1896) obtained slight but nevertheless well-defined reaction in ten out of thirteen patients suffering from various maladies, the tuberculous nature of which was suspected, but could not be affirmed, while in three cases of undoubted pulmonary tuberculosis with bacilli in the expectoration no appreciable reaction occurred. Grasset and Vedel used minute doses, not exceeding .0002 to .0005. De Renzi quotes Pieper, Rietzkow, Senn, and Verneuil, who reached the conclusion that Koch's injections are not a sure method of diagnosis in tuberculosis of the internal organs, and also Von Jaksch, who thinks Koch's method has a high diagnostic value. De Renzi himself says, "Nevertheless, it must be admitted that tuberculin in a majority of cases can be used as a diagnostic agent." R. Koch (*Deutsche Med. Woch.*, No. 14, Vol. I., April, 1897), in his recent publication on a "New Tuberculin," states that Dr. Nietner will soon publish the results of the application of the tuberculin test to one thousand cases.



Case i.

Temperature chart of patient who received three injections of tuberculin without resulting reaction.

Sarcoma, carcinoma, syphilis, and actinomycosis have been said to react to tuberculin, but in the instances quoted the presence of tuberculosis in conjunction with the above-mentioned diseases was usually not excluded. Before condemning the test as at fault when reaction occurs in apparently healthy individuals, it should be borne in mind that autopsies made on persons dying of other diseases show some unsuspected tuberculous focus to exist in from thirty to forty per cent. of those examined.

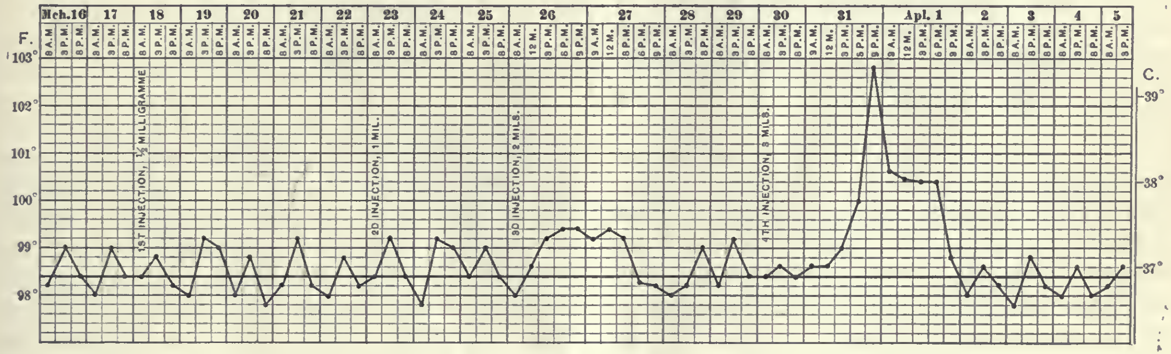
My own experience with the tuberculin test during the past five years has been principally in the direction of its occasional use to determine the presence or absence of suspected pulmonary tuberculosis when diagnosis could not be made by ordinary means, and has been limited to fourteen cases, seven of which were positive and seven negative. The highest dose given was three milligrams. In the positive cases reaction was obtained in six with a dose of two milligrams or less. In one, however, an injection of three milligrams was necessary before a well-marked and typical reaction took place. The temperature in six ranged from 100.2° to 102.5° F. at the height of the reaction, and the symptoms were of moderate intensity and soon abated. In one case only the temperature reached 104.2° F. Symptoms indicating reaction came on in six cases within twelve hours, and in one they were not well defined until twenty-two hours after the injection. In six of the cases the fever had entirely abated within twenty-eight hours; in one it lasted forty-eight hours. In all of these after the temperature returned to normal no unusual rise took place, and the general condition of the patients was within a week apparently the same as before the tests were applied. What slight physical signs were present seemed accentuated for a time within twenty-four hours after the injection in all but two, in both of which the previous examination of the chest had proved entirely negative. In these no abnormal sounds were developed by the injections. The tests were made in one case in 1893, in two in 1894, in two in 1895, and in two in 1897. One of these patients has been lost sight of and reported as dead; the others have shown at some time or other clinical evidence of pulmonary tuberculosis.

In the seven negative cases no appreciable rise of temperature occurred. Two of the patients have passed from under observation, but the others have all remained well thus far. The test was applied in two cases in 1893, in one in 1894, in two in 1895, in two in 1897.

The history of two cases, one negative, the other positive, is briefly given, with temperature charts, as being instructive. The rational symptoms in both cases were obscure and very similar. A physical examination of the chest proved inconclusive, and in both cases no positive diagnosis as to the presence or abscence of tuberculosis could be made before the test was applied. The chart in Case 2 shows a typical tuberculin reaction occurring at the fourth injection of three milligrams, which in this case was rendered necessary, the smaller doses having given but equivocal evidence of the presence of a latent tuberculous process.

Case I.—Miss A., aged twenty-eight years. Family history good. Has lost ten pounds during the last three months. Is somewhat anemic, tires very easily, and has had some cough with but little expectoration for the past six weeks. Appetite poor, and digestion at times troublesome. Has no fever, but has occasionally perspired a little at night. Expectoration repeatedly examined shows no bacilli. Physical examination of chest inconclusive. The vesicular murmur is very faint, and expiration somewhat prolonged at right apex. This patient was sent to the mountains as a case of suspected pulmonary tuberculosis. The test was made in 1893, and the three injections given produced absolutely no rise of temperature. The cough disappeared within two weeks, and the patient was allowed to return to New York, where she is now living in excellent health.

Case II.—Mr. B., aged nineteen years. Father died of phthisis; two brothers and a sister are well. A year ago began to notice that he tired easily and lost some weight. Has never been up to his usual standard of health since, though he has had no marked symptoms. Has no cough except at times when he catches cold; has no expectoration except at such times. Expectoration examined then showed no bacilli. Temperature when he gets tired or has a cold reaches 99.5° to 100° F., otherwise generally normal. Had typhoid fever in 1890. Lungs examined several times by specialists, but nothing found. Came to the mountains seven months ago, and has gained nearly ten pounds. At present is up to his normal weight. Still tires easily, but is desirous of entering college if no serious disease exists. This test was made in March, 1897. The first two injections produced no effect whatever. The third, of two milligrams, was followed by a little discomfort, and it will be noticed that the temperature, which stood at 99.6° F. twelve hours after the test, did not fall as usual the next morning, but remained above 99 until 6.30 P. M. As this seemed suspicious, a third injection of three milligrams was given four days later. A typical reaction ensued. At 6 P. M. he was a little chilly, had some pain in the limbs, and went to bed of his own accord. At 10 P. M. his temperature stood at 102.8° F. It fell during the night to 100.6°, but did not return to normal until 6 P. M. on the day following the injection. Within two days he said he felt as well as ever; no rise of temperature has taken place since, and he seems in his usual health. A careful examination of the chest during the reaction was negative.



Case 2.

Temperature chart showing reaction after four injections of tuberculin had been given.

In the absence of any well-defined rules founded upon the experience of others at the time I began to use the test, the method I adopted has been a purely arbitrary one and I make no claim for its being the best or the most reliable, although as far as my own personal experience goes I have as yet seen no objection to it or any reason to modify it.

The range of the patient's temperature is ascertained by taking it at 8 A. M., 3 P. M. and 8 P. M. for three or four days before making the test. The first injection should not exceed five milligrams, and if any fever is habitually present should be even less, and is best given early in the morning or late at night as the typical reaction usually begins, in my experience, within six or twelve hours. Such a small dose, while it will often be sufficient to produce the looked-for rise of temperature, has under my observation never produced unpleasant or violent symptoms. An interval of two or three days should be allowed between each of the two or three subsequent injections it may be necessary to give, as reaction in very rare cases may be delayed for twenty-four or even thirty-six hours. On the third day a second dose of one milligram is given, and if no effect is produced, a third of two milligrams three days later. In the great majority of cases of latent tuberculosis an appreciable reaction will be produced by the time a dose of two milligrams has been reached. If no effect has been caused by the tests applied as above I have usually gone no further, and concluded that no tuberculous process was present, or at least not to a degree which need be taken into account in advising the patient, or which would warrant insisting on a radical change in his surroundings and mode of life. If some slight symptoms, however, have been produced by a dose of two milligrams, it may be necessary to give a fourth injection of three milligrams in order to reach a positive conclusion. Nevertheless, it should be borne in mind that in a few cases the exhibition of even larger doses may cause reaction and indicate the existence of some slight latent tuberculous lesion, and the test should not, when applied within the moderate doses described, be considered absolutely infallible.

No evidence in connection with the tuberculin test as applied to man and animals has been forthcoming thus far from those who have made use of it which would tend to sustain the general impression that this method is necessarily dangerous and tends invariably to aggravate the disease, and my own experience has developed nothing which would seem to confirm this impression. It is evident that the size of the doses given has much to do with the limitations of this method for usefulness and the correctness of the conclusions reached by its application. The tuberculin used is also a matter of some importance in determining the dosage, as different samples vary considerably in their efficiency. The minute amounts adopted by Grasset and Vedel, *i.e.*, from .0002 to .0005, while they have the advantage of absolute safety, may lead into error, as they are insufficient, on the evidence of these observers themselves, to cause reaction in cases proven to be tuberculous by the presence of the bacillus in the expectoration. If, on the other hand, the test be pushed to the injection of such large amounts as 10 milligrams or more, as advocated by Maragliano, such doses are by no means free from the objection of occasionally causing unpleasant and sometimes dangerous symptoms; and even if the amount given be not carried to the dose of 10 milligrams, which is known to produce fever in healthy subjects, it is likely that, on account of individual susceptibility or the presence of some other morbid process in the body, reaction will be found to occur with the larger doses when no tuberculous process exists. The adoption of an initial dose so small as to guard against the absolute possibility of producing violent reactionary symptoms, and the graded increase of the subsequent doses within such quantities as are known never to produce reaction in healthy individuals, would seem to afford the best protection against unpleasant results and misleading evidence.

It is greatly to be desired, however, that more light should be thrown by additional studies on these points, and that the best method to be employed in making the test and its limitations be more accurately defined by evidence derived from a more extended and varied experience in its use.

NOTE.—Since the above was written, and while it was in the publishers' hands, a paper on the Diagnostic and Therapeutic Value of Tuberculin was read by Dr. James T. Whittaker before the Association of American Physicians, and although I was not present at the meeting, and have as yet seen only abstracts of his communication, it is evident that Dr. Whittaker's extended experience with tuberculin has been in the main similar to my own. The doses he has made use of are larger than those I have employed, but his experience as to the value of the test when intelligently applied, and its freedom from injurious effects, has been the same as mine.

THE PROGNOSIS AND TREATMENT OF ACUTE GENERAL PERITONITIS.[1]

BY ROBERT ABBÉ, M.D.,
OF NEW YORK.

TWENTY years ago, the dread of peritonitis after operations within the abdominal cavity where previous inflammation did not exist, was still the bugbear of surgery. It has gradually occupied a lessening position of seriousness in the calculations of the operator, until to-day the surgeon, who is properly cognizant of the powers of the peritoneum to aid him when respectfully treated, completes his work (no matter what immediate soiling has occurred, be it extravasation of bile, urine, feces, or pus), with slight apprehension that post-operative peritonitis will occur. The once-dreaded invasion of the peritoneal cavity has become a matter of safe conduct when the operator is the invader. Nevertheless, this same cavity has become a battleground of great interest in the surgical field to-day, when not the surgeon, but germ-laden matter, is the invader, and precedes the surgeon by many hours. Here the race becomes unequal. A death-dealing blow has been dealt to the human body in one of its most vital parts, a blow from which it is possible to rally, under some circumstances, by intrinsic powers of resistance, but which, under most conditions, is followed by an encounter, the outcome of which will often depend on extrinsic aid from the physician and surgeon.

---

[1] A contribution to the discussion upon "Peritonitis" at the the Fourth Triennial Congress of American Physicians and Surgeons, Washington, D. C., May 4, 5, and 6, 1897.

It is to the study of this most important and narrowing field that our attention is turned.

That the peritoneal cavity is not equally impregnable in all its parts is a well-established fact. Not that the same susceptibility does not exist in all anatomically similar portions of its surface, but from varying contour, or proximity to actively moving viscera, it transpires that the greater part of those invasions which originate in the pelvis, or in the fossæ outside the colon, or in a less measure in the area anterior to the stomach and liver and above the colon, become localized within a few hours, and are under the control of Nature's reparative processes in the confines of quickly built up lymph walls; while a discharge of offending secretions into the more central part among the small intestines becomes a grave menace, from causes the principal of which seems to be the difficulty encountered in throwing up barriers in the presence of quick-moving intestinal coils, which rapidly distribute the infection.

Hence, we will see that the location of the invasion, independent of the quantity and virulence of the material spread about, has much to do with determining the gravity of the case and the need of action. The scholarly treatment of the subject of general peritonitis, in all its minor and major phases, by Treves and other writers, and the graphic delineation by Dr. Senn of the varieties and classification, impress upon our minds the value of thorough understanding of the nature of peritonitis and the methods adopted by Nature to save life. They prepare us to accept the dictum that all peritoneal invasions by infectious processes, of which we shall speak, are essentially fraught with the greatest peril. Although general peritonitis may originate in any portion of the cavity, we must exclude from our thoughts in this discussion all limited forms, no matter how grave their concomitant symptoms. We know that an intra-abdominal abscess or slight infection may be accompanied by so grave symptoms that, to the clinician, it may seem to be a case of general peritonitis, and a surgeon may even wrongly report operation on general peritonitis, because he has opened an enormous abdominal abscess which had crowded the uninflamed intestines into the upper part of the abdomen.

The grave form of acute general peritonitis which we are to consider is one which is caused almost universally by the rupture of some one of the hollow viscera (stomach, intestines, appendix, or bladder), and for the practical surgeon need not be classified on any but a clinical basis. We must accept the universal bacterial origin of peritonitis, and regard the victim as poisoned by the septicemic infection. Apart from all other considerations we must say that acute general peritonitis shall include only those cases in which the infection is not confined by any lymph barriers. The stage at which it is seen will determine the area of the peritoneum invaded. The affection is the same whether it include half or all of the entire peritoneum—for who can say when the last few inches are affected? The case which we operate on to-day and find universal had spread to only half the abdomen yesterday and six hours earlier to one-quarter of its area. The surgeon has to form an estimate of each particular case at the time of operation by the naked-eye appearances and thus classify it as to gravity. If he has been fortunate enough to inspect it by early operation he will find most various appearances all illustrating an early stage of a disease inevitably advancing to a fatal issue. The one essential feature that allows a case to be classed as acute general peritonitis is that there are no boundary limits. Given a turbid, semi-purulent or purulent effusion about inflamed small intestines arising from perforated stomach or gangrenous appendix, with no effort of Nature to wall it in, and the fatal end of the case is not far off unless arrested by the surgeon. Septic infection has already occurred and Nature has failed to wall it in.

The only subclassification of this form of peritonitis is into the early and late stage. Both are equally grave if left to Nature.

Opinion has been growing skeptical as to the value of operation in this form of peritonitis in any stage. Speaking of general diffused non-tuberculous peritonitis, Treves says: "I am doubtful if a single human life has been saved by surgical interference in a genuine case of peritoneal toxemia." Richardson says: "In a large number of cases of general peritonitis, verified by bacteriologic examination, the result with hardly an exception has been fatal in my hands under any method of treatment." Weir says that he had never been able to save a patient nor had he seen one saved. Von Winivarter, after a large experience, writes: "In not a single case where the exudate had a fecal odor have I succeeded in saving my patients, all have succumbed to the septic intoxication. . . . We possess no means of checking a peritonitis of septic character." Regnier says: "Laparotomy and lavage are unavailing for the cure of a true general peritonitis. The various cases we hear of are cases of large encysted purulent collections." Delorme says: "I have operated on many cases of general peritonitis and I have lost all my patients."

Facing this pessimistic opinion, which is echoed from many sources, it seems evident that the optimism of those who report from thirty to sixty per cent. of cures, is born of a misunderstanding of the variety of the disease discussed. Let us then make no mistake in appreciating the character of the disease.

As I have already stated the only warrant for classing cases under this head is the presence of reasonably extensive involvement of some part of the small intestine from foul contamination, which is absolutely not limited by any boundary adhesions. As far as septicemia goes, they are all septic, and under the above conditions practically guarantee an ultimately fatal issue under expectant treatment. Demonstration of the presence of noxious bacteria in the exudation has been so constantly shown that it may be admitted to be universal. Acute general peritonitis is an *a priori* argument of their existence.

The variety of the bacterial flora corresponds with that found within the intestines. Elaborate research has already demonstrated the streptococcus and bacillus coli commune as most uniformly present. Therefore, we are prepared to study the prognosis of *unlimited peritonitis* from an operative point of view, regarding it, if fairly widely developed, as being on the high road to a fatal issue.

The effort made by the system of the patient to protect and rid itself of the parasitic assault, is a complicated and beautiful one. The power of the peritoneum to rapidly remove large quantities of fluid, introduced experimentally in animals, as studied by Wegner and others, demonstrates that from three to eight per cent. of the animal's weight of fluid can be taken up in an hour—equivalent to the entire weight in one day. Murcatello demonstrated, also (*Virchow's Archives*, 1895), that the current of absorption is toward the diaphragm, which fact is of practical import. Carmine particles suspended in fluid are quickly carried through the intercellular openings in the peritoneum covering the diaphragm into lymph spaces beneath, where direct communication is had with the mediastinal glands. Here the parasites can be found arrested in five to seven-minutes' time if the animal is held head downward.

Before the visceral peritoneum begins absorption into the lymphatic system of the mesentery that which lines the diaphragm has given exit to bacterial infection and leucocytes, which are speedily taken into the blood current and sent to the large abdominal organs—the liver, spleen, and kidneys.

Experimental research shows that when a small amount of infectious culture of intestinal bacteria is injected (a cloudy emulsion of 5 or 10 c.c.) it can be disposed of without fatal effect. A small quanity produces diarrhea; more, a local peritonitis; still more, a fatal fibropurulent peritonitis—and a larger dose, acute fatal sepsis, without peritonitis. Examination of the survivors show no streptococci in the peritoneum 5½ hours after injection of small quantities. The experiments of Barron and others, however, show that a very minute quantity of fluid from an inflamed part (such as fluid from puerperal peritonitis) produces much graver symptoms than a larger quantity of a culture from the same germ. The destruction of bacteria by phagocytosis, and the unexplained bactericidal action of blood-serum, are coincident methods called into action in the emergency and need no description here. When the injection is severe they are inadequate and every organ teems with bacteria soon after pronounced septicemic symptoms appear.

With such recognition of the power of the peritoneum to rid itself of small toxic doses, we turn to the demands made upon it by disease and accident. Taking the experience of hospital surgery as representing an average we find that acute general peritonitis results in the majority of cases from infection starting from the appendix. Second to that, perforating gastric ulcers, intestinal traumatisms, ruptured pelvic abscesses. Ruptured urinary and gall-bladders occupy a relatively smaller place.

With the nature of the invading medium, it is evident, the virulence of the attack must vary. A discharge of stomach secretion into the peritoneum seems not to be so quickly toxic as a minute quantity of active poison pent up in an already inflamed appendix, yet by its eroding action on the endothelium paves the way for absorption soon after. So also with normal urine or intestinal contents not in a state of inflammatory ferment at the time of invasion. In such cases septicemic symptoms supervene some hours after the accident. Perforating gastric ulcer, if it has time to leak slowly into the peritoneum, will almost surely be controlled by adhesions, and the alert operator may save general invasion by incising the epigastric abscess.

Most perforations, however, occur after a meal, and general peritonitis is set up simultaneously from the stomach to the pelvis. The degree of inflammation found will be in exact ratio to the lapse of time before operation.

Recent statistics show that, up to five years since, no operative case for perforating gastric or duodenal ulcer had recovered. Weir has recently collected 97 operations, with 22 recoveries, and to his statistics I am able to add a summary of twenty reported later, three of these being my own. In these additional 20 general peritoneal extravasation occurred in 18, and of this number 12 recovered and 6 died. Out of the 12 recoveries operation was performed within ten hours in 7 and after twenty-four hours in 5, showing the value of prompt action. Of the six fatal cases in all but one operation had been delayed until after the first day. In two fatal cases the peritonitis was practically cured, but the patients succumbed to septic pneumonia as late as the seventeenth and twentieth days. Weir says, in reviewing his statistics: "More than half of all the patients operated on in the first twelve hours recovered, the mortality being 39 per cent.; while of those operated upon from twelve to twenty-four hours after perforation, 70 per cent. died, and of those who came to operation after the first day, 87 per cent. succumbed." In conclusion, he says: "The happy result of operation is dependent more upon its early performance than upon any other factor." My own feeling is most hopeful that future contributions to this subject will show that the earlier we can operate on these cases, the more surely will we be able to combat the disastrous accident.

In gunshot or stab or penetrating wounds of the abdomen there is a universal consensus of opinion that operation at the earliest possible moment is the only justifiable attitude. The surgeon can never be absolutely positive some organ is not injured or that there exists concealed extravasation until he has seen the invaded part. If it be a slight stab wound, or if shock is greater than will warrant anesthesia, it is incumbent on the surgeon to make an incision or an extension of the wound under cocain anesthesia, and if nothing be discovered he may then be justified, and only then, in awaiting symptoms. If he finds perforation or hemorrhage, a temporary arrest of the flow will be conservative until two or three hours have given the patient time to recover from shock. The statistics of gunshot wounds corroborate the value of promptness, as seen in every other phase of abdominal work. Of 39 cases operated on within twelve hours, 18 recovered, while of 22 after twelve hours, only 5 recovered. Likewise in rupture of the urinary bladder, which was uniformly a fatal accident until recently, the mortality has been reduced from 90 to 50 per cent. during fifteen years. Sieur's paper reports 34 cases and 14 recoveries. Schlanger notes 22 operations and 10 recoveries. The evidence is accumulating that early cleansing and draining will insure a prompt recovery, unless cystitis be previously present when the chance of grave peritonitis is enhanced. So also if the gall-bladder be inflamed at the time of injury, the bile is swarming with bacteria, notably the coli commune, which have worked back from the duodenum, and septic peritonitis is imminent unless quick and thorough precaution be taken. Normal bile, however, will be fairly well borne and disposed of by the uninflamed peritoneum.

The phase of acute general peritonitis from perforating typhoid ulcer has seemed to me to differ but little in its course and treatment from that following ulceration of other parts of the alimentary canal. The patient's lower vitality does not militate so greatly against recovery as one would imagine. The peritoneum is able to throw reparative lymph about a slow perforation, though usually it is overwhelmed by a sudden liquid extravasation. The beneficial results of interference are shown by the case of Van Hook, which, as yet, stands unequalled. He operated at two in the afternoon in a case where rupture occurred at five in the morning (nine hours before). Extravasation had taken place wide of the ulcer. The opening was sutured, the abdominal cavity thoroughly washed out, and the patient rescued from collapse, and saved. Excluding all doubtful cases, Finney finds 11 recoveries after 45 operations, showing a success in 26 per cent.—certainly a very admirable showing in the face of practically certain death. The evidence, as he shows, is clearly in favor of early operation. The most striking recoveries were among those operated upon twelve hours after the accident.

It is well recognized that in this trouble there is a marked signal symptom of the beginning perforation. The patient has "sharp continued abdominal pain coupled with nausea." As in gastric perforation the patient feels as I have had them express it either a "tearing pain" or as if something had given way. Hence, the attending physician has in most cases every reason to suspect the nature of the disaster, and little excuse for masking the symptom by morphin while waiting for peritonitis to set in before seeking surgical aid.

After the foregoing considerations we are now able more intelligently to consider the prognosis in that disastrous condition seemingly more common every day, *viz.*, acute general peritonitis of appendical origin. Granted that ninety per cent. or ninety-five per cent. of mild attacks of appendicitis pass over without grave results, there still falls to the lot of the surgeon that unhappy group of septic cases which are presented to him for cure by the too often delinquent practitioner after from two to five days of hopeless expectancy. Of this type, with non-limited inflammation, all are in various stages of septicemia, and the dullest observer must admit that, be it early or late, the patient is on the highway to more profound infection and inevitable death. The literature of the last two or three years teems with references to individual cases and opinions, showing confusion of classification and reporting oftentimes doubtful cases.

I have chosen therefore to ask you to consider a very few reported consecutive cases representative of this class.

Two years since McBurney chose a group of twenty-four cases distinctively of this type operated on by himself during the previous five years and gave brief details of each, sufficient to identify it as justly classified. He also regards general peritonitis as including those not only which are seemingly universal but such as involve half or a quarter of the intestinal surface and are spreading without barrier at the time of operation. Of his twenty-four cases he saved fourteen. One reads though that in some cases limiting barriers had been thrown up but had subsequently burst and scattered the pus far in advance among the coils of intestine. McCosh, also, in a paper recently read before the Surgical Society chose, among his hospital cases, eight during the past two years and forty-three during the previous seven, which he had submitted to radical operation. Of the forty-three in the earlier group thirty-seven died (86 per cent). Of the eight during the past two years two died. Of all the fifty-one cases thirty-nine died (or 76 per cent). He has carefully confined his choice to cases of distinctly generalized peritonitis.

In my own practice I have chosen with the same point in view thirty-three cases, all that I have operated on during the past five years from among several hundred laparotomies. I would also add ten well-observed cases ably reported by Lockwood (*L. Clin. Jour.*, April 1, 1896) and nineteen consecutive cases during two years by Koerte (*Berlin. Kl. Woch.*, Aug., 1892). It would be unnecessary to enlarge this list for present discussion, and we may fairly say that this group of 137 cases are representative, and would be duplicated in consecutive work by most operating surgeons. As already remarked it is only fair to the discussion to divide these into two groups, representing an early stage and a late stage as nearly as possible. A picture of the two types would be represented by what may be presumed to be the condition of the same patient operated on at the end of twelve hours or neglected until the third day.

From the milder class are excluded all those where clear serous effusion is found free, and from the second cases those where pus is scattered from an abscess at operation, or just prior to it, even though it be found smearing the intestine beyond confines.

In the first picture, the early stages, a day or two after a sharp onset of symptoms, operation will release turbid or semipurulent fluid, which will flow from between presenting coils of intestine before the appendix is reached, and will uniformly be found in considerable quantity in the lower pelvic pouch. When the operator has dried all presenting parts, he draws the dusky, inflamed intestines toward him, and finds no barriers of lymph adhesion; but as he sponges between the coils and advances into the center of the small intestine area, there is less and less appearance of inflammation. When the visible evidences are less, he thrusts sterile gauze pads still further into the interintestinal spaces, and later, on withdrawing them, finds them wet with clearer effusion than that already removed. He rests satisfied. The appendix in these cases may be either slightly perforated or gangrenous, free among the intestinal coils, or hanging loosely in the pelvis. It is bathed in foul-looking fluid, more turbid than appears elsewhere, and usually has a slimy, virulent-looking coating of non-adhesive exudation. If not thinned by gangrene of its coats, it is highly inflamed and hard.

If treated expectantly it will represent the second class in from one to three days, and on incision thin pus (usually offensive) will stream out of the operative wound—will be found floating the bowels out of the pelvis, and come equally from the opposite side of the abdomen, or in the median line above the navel. The intestines are thickened or even granular, and reddened lymph patches are loosely and irregularly adherent. It is no wonder that surgeons stand appalled before this class and are skeptical as to their ever being cured.

Taking the class mentioned as the most fair that I can find for study we have the following showing:

McBurney, 24 cases, 16 recoveries; McCosh, 50 cases, 12 recoveries; Abbe, 33 cases, 9 recoveries; Lockwood, 10 cases, 3 recoveries; Koerte, 19 cases, 6 recoveries. Total—137 cases; 46 recoveries. It is possible in many of these to divide them into the two classes previously mentioned.

In my own, of which I have clear records, I can assert that of the 33 cases, 6 were of the milder type but progressing rapidly when operated upon, and 27 were of the grave type. Of the mild type 5 were operated on early, and 1 on the fifth day—all recovered. Of the grave 11 were operated on within two days, 3 recovered, 8 died; 16 were operated on from two to five days after the attack—all died.

Of the reported cases of McBurney and McCosh it is not easy to thus classify many of them, but choosing 28 cases, in which the time of operation is indicated, there were 18 of the grave type, and 10 of the milder. Of 6 grave cases taken within 1½ days, 4 recovered, 2 died; of 8 grave cases taken within 2½ days, 4 recovered, 4 died; of 4 grave cases taken within 2½ days, all died. Of 10 cases of milder type, 3 cases taken within 1½ days, all recovered; two cases within 2½ days, all recovered; 5 cases after 2½ days, 1 died. Of 19 cases of Koerte, 16 operated within 4 days, 6 recoveries; 3 over 4 days, all died.

For a summary then we may say that choosing only those 16 which are certainly of the milder type, judging from personal knowledge or the records, only 1 died. Of the graver type, 64, where the time is noted, the 17 recoveries were all obtained inside of 2½ days. There is but one logical deduction from this review—and that corresponds with the same, drawn with regard to perforations of the stomach and intestines—namely, that the element of time is the one of greatest importance. The earlier the operation the greater the hope. Only 1 death occurred in 16 slighter forms of advancing general infection, and almost no case of the graver type recovered after 2½ days from the hour of attack, the earlier periods showing most recoveries.

There is one point I have discovered in the review, that, of numerous cases where recovery takes place, albumin or casts are not found in the urine. I ask careful consideration of this by future reporters because it would seem that where the kidneys are choked up by the bacteria of septicemia it is practically useless to operate.

If time permitted, I would gladly give some thought to the evidences which distinguish a true case of beginning dangerous peritonitis from the milder local troubles which often begin with seemingly the same violence.

Are there any entirely characteristic symptoms?

A study of the initial signs in cases which have come to operation and been proved has shown me that uniformity of symptoms is entirely wanting. A persistent diffused tenderness spreading to the opposite side of the abdomen is very grave. A board-like stiffness of both sides of the abdomen is suggestive. Tenderness at a point in the rectum as high as the finger can reach in the median line is a sure index of either an inflamed appendix hanging over the pelvic brim, or an acute peritonitis. A pulse that is rapid and quick, or "snappy," is almost a sure index of septic toxemia, and, if it persists more than twelve hours, calls for interference.

Vomiting will usually occur once with most mild attacks, but, if persistent, indicates mischief. The tongue may be clean and moist and the eye bright in one-third of the cases of grave peritonitis, even after two or three days.

The facies of abdominal inflammation is more often a late symptom.

Thoracic respiration is very often seen when spreading peritonitis prevails.

The temperature is frequently but little elevated during the first day or two, while the pulse may be showing great agitation.

These danger signals may serve to aid diagnosis before profound toxemia sets in; when the surgeon can do nothing.

Regarding treatment, substantial progress has been made in determining the lines of action.

There is but one opinion regarding the cleansing of the abdominal cavity when only the lower segment has as yet been invaded. The moment the surgeon sees septic fluid, he sponges it away before it can be scattered. He mops the presenting bowels with sponges in clamps, dripping wet with hot salt solution (ʒ iss to a quart), and dries them again before drawing other coils into the field of inspection. As soon as parts are found not much inflamed, he pushes a sterilized gauze tamponade, properly folded, among the bowels far away from the field of work. This has a tape sewed to it, to which a clamp is fixed and left outside the wound. One or two such tamponades may be thrust upward and across the abdomen before the pelvis is cleansed, to which much attention is *always* to be given. This being thoroughly mopped out, a light packing of mild iodoform gauze is to be placed in the pelvis, and a short way among intestinal coils elsewhere, especially if the gauze tamponades now removed prove to have come out wet, absorbing the thin effusion from a distance. The abdominal wound should never be closed in any septic case. It wastes time, confines infection, and prevents drainage.

In the grave cases, a long median incision, or two lateral ones, will always be needed. The lumbar drainage incision will only be necessary when the median cut is used.

The question of drainage has been thoroughly settled in favor of ample gauze packing as against rubber or glass tubes.

The lymph barrier quickly thrown out by the peritoneum wherever the gauze is in contact at once forms a boundary line, beyond which one process is going on, namely, absorption, destruction, and elimination of the marginal infection, already entrapped, while at the site of packing the current is reversed and everything is sucked into the gauze and removed.

When infection has been widespread there is but one alternative—irrigation. By flushing the inter-intestinal spaces systematically with hot salt water, as hot as the operator's hand can bear (which will be over 105°, usually), these effects are produced. The water cleanses and stimulates the patient amazingly. One sees the pulse respond at once and remain steady long after the operation, and the absorbing power of the washed endothelium is diminished. This has been shown by experiments of Kinscherf on animals where doses of strychnin or bichlorid of mercury left after irrigation were not absorbed, while the same put into the peritoneum of dogs not irrigated were fatal. Thus the toxin absorption is temporarily arrested, while the patient fights for time to discharge the burden already taken up.

In the large abdominal incisions in bad cases, it is wise to leave the wound widely open, the gauze will hold back the intestines, and abdominal straps and binder will support the abdominal walls.

If the intestines are distended with gas and fluid feces it is well to let them come out of the abdomen, receive them in hot towels in charge of an assistant, and prick one or two prominent places with a knife to evacuate gas and noxious excreta, which is washed away with a constant hot stream. Through one opening there should then be injected a syringe full of saturated solution of Epsom salts and the puncture closed. I have done this on three occasions during the past three years, but only in the very worst cases.

McCosh, however, advises in all bad cases to pass such a dose of salts through an aspirating needle into the bowel, and close the aperature with one suture, which I heartily endorse as a routine procedure. It cannot be vomited, it excites downward peristalsis, and as it aids to carry off impurities, it proves of the greatest value.

In regurgitation lavage of the stomach should be done before and after operation, and repeated as soon as regurgitation is renewed.

The rectal tube to relieve distention by gas is of inestimable value, and its use not infrequently marks the turning point in the disease by promoting downward peristalsis.

Some of the most brilliant recoveries I have had have been where the attending doctor has been ineffectually plying the patient with calomel or physic, which acted only after operation, or where a good dose of calomel taken after operation has rid the body of all noxious excretions on the second or third day.

The value of an ice coil, or light broad ice bags after a general peritonitis, cannot be overlooked. I have great faith in cold thus used to retard the inflammatory action and bacterial growth either before or after operation. Moreover, it is almost uniformly grateful to the patient.

I will not detail other restorative measures which must be plied on general principles. Strychnia 1-40 gr. every two hours is sometimes necessary, and in cases of severe pain when the patient is well out of ether, morphine, hypodermically, is rather helpful than otherwise.

In conclusion, I would say that close study of the bad cases of general peritonitis shows it to be one of the most absolutely fatal maladies with which we have to deal. It has also been demonstrated that logically and statistically the earlier the operation on the lines delineated the better the prognosis. It has been further shown that even in the bad form if operation be done and a masterly irrigation carried out there still remains a chance for life if the period elapsing be not more than two and one-half days. In cases where albumen and casts show in the urine it is proof enough that the system is already overwhelmed and the kidneys and other glands are choked and the operation hopeless.

The burden of responsibility then for fatal issues in so many cases lies not with the surgeon so much as with those who withhold from him the opportunity to render the prompt aid which we have shown is the only chance. The ideal success may be accomplished in the future not more by new methods than by new opportunities. The ideal operation may be the old method under ideal circumstances as to time.

NOTES ON THE ULTIMATE RESULTS OF THYROID FEEDING IN CRETINISM, WITH SPECIAL REFERENCE TO THE EARLY STIGMATA OF DEGENERATION.[1]

By H. H. VINKE, M.D.,
OF ST. CHARLES, MO.

CRETINISM is a condition of complete degeneracy dooming its victim for life to a degree of mental and physical development not much advanced beyond that of infancy. Metabolism appears to have come almost to a standstill in these cases. Careful scientific research has developed the fact that the immediate cause of this rare affection is an absence of thyroid secretion, resulting either from an entire absence of the thyroid body or from total disorganization of that gland. Thyroid feeding in these cases has been followed by a reanimation, so to speak, of the centers controlling normal metabolism, and by renewed physical and mental growth.

Improvement in the physical condition of these patients is first noted; they begin to grow rapidly, the face assumes a more intelligent expression, and there is an apparent return to a normal condition. Intellectual improvement is as constant as improvement in the physical condition, but not so rapid, which is quite natural when it is remembered that the mind of a cretin is not advanced beyond that of an infant. A complete return to a normal condition undoubtedly depends upon the length of time the disease has existed when treatment is undertaken. When early, a complete cure may reasonably be expected; when undertaken late, after the disease has persisted for years, during which period all growth is practically in abeyance, it is practically impossible to regain all that has been lost, although considerable improvement may confidently be looked for. Normal thyroid secretion is most important to the economy during its developmental period, but is indispensable at all times, for, after the complete ablation of the thyroid gland in the adult, cachexia strumipriva or surgical myxedema is known to ensue. We may, therefore, safely assume that in cretinism thyroid feeding must be continued throughout life.

---

[1] Read before the Tri-State Medical Society at its annual meeting, held at St. Louis, Mo., April 6, 7, and 8, 1897.

Unless we hold that cretinism is an affection of different degrees, complete absence of thyroid secretion entails the gravest forms of the disease, the milder forms resulting when the thyroid gland continues to secrete some thyroid juice which is insufficient in quantity or changed in quality. In the latter case, the administration of healthy thyroid juice might in time excite normal functional activity of the thyroid gland. It is probable, however, that the human organism exhibits the classic symptoms of cretinism only when there is a complete annihilation of the thyroid secretion, and that in cases where there is simply a lack of sufficient secretion, merely a few evidences of degeneracy will be found.

The opinion has been advanced that when in time this earth ceases to be a suitable habitat for the species homo, the last state in the radical degeneracy will be a condition not unlike that of cretinism, but as yet cretinism is comparatively rare. Much more frequently, however, do we meet with marks of defective development or stigmata of physical and mental degeneracy. Prominent among the former are: A bulky head out of proportion to the body, persistence of the anterior fontanel beyond the second year, a meager growth of coarse and dry hair, late irruption of the teeth, goiterous degeneration of the thyroid gland, modification of the voice; dry, coarse, and loose skin, general obesity with characteristic softness of the hypertrophied adipose tissues, a prominent abdomen, rachitic deformities, such as curvatures of the long bones and of the spine, persistent low temperature, etc. Stigmata of mental degeneracy comprise lack of vivacity, torpor, sopor, and the different degrees of deficient intellectuality, of which an enfeebled mind is the mildest and idiocy the severest form. Such marks of degeneracy we would expect to find in children who are backward, whose growth is stunted, and who walk and talk later than normal children. In fact, unduly retarded physical and mental growth, even in the absence of the anomalies and deformities referred to, is suggestive of insufficient thyroidization. Assuming that all these marks of degeneracy depend upon defective metabolism, of which a lack or perversion of the thyroid secretion is a prominent factor, the field of applicability of thyroid feeding would be considerably widened, for, inasmuch as thyroid feeding is followed by such excellent results in cretinism, the conclusion that thyroid feeding would be equally successful in the earliest manifestations of degeneration might be drawn without undue temerity.

The importance, then, of recognizing the earliest stigmata of degeneration is obvious, for, by judicious treatment with thyroids we might not only expect to prevent ugly deformities, but also complete degeneracy. I wish to call attention here to the fact that we are indebted especially to Schiff, Horsley, and Murray for all we know of the functions of the thyroid. By careful experiments on lower animals these scientists were enabled to determine not only the function of the thyroid body, but also to point out the remedy for disturbed or annihilated function of that organ.

For the past six weeks I have been treating a child with thyroid extract in whom some of these marks of defective metabolism were apparent. Owing to the poor health of the mother, this little girl had to be fed from birth on boiled, sterilized, and condensed milk, different commercial foods, etc., and as a result of this feeding the little one saw few well days during the first two years of her existence. Gastrointestinal disturbances were constantly present, slight and unimportant at times, and again so severe as to require the attendance of a medical adviser, when new medicines and some new food would be prescribed. It is surprising indeed that a large number of physicians should take so little interest in such an important subject as infant-feeding, and that they should be willing that manufacturers of foods should solve for them such an important problem. At the time that the child was put upon thyroid treatment I found the head out of proportion to the body and much larger than that of her sister, who is two years older. Her hair was coarse and dry and looked not unlike that of a doll. The skin was coarse, loose, and flabby over the entire body, and usually moist, with an offensive sweat. Over the chest and abdomen there was a rash, probably the result of inflamed sweat-glands. Distinct depression over the lower ribs on both sides, immediately under both nipples, was evident. Myxedematous deposits were found on the dorsal surfaces of both feet. Though nearly three years old, she could not support her body on her feet, and her vocabulary was limited to a few words, and these could be understood only by her parents.

It has been determined that the dose of thyroid extract is from ½ a grain to 1 grain a day for children under two years, and from 1 to 3 grains daily beyond that age. As much as 6 grains daily has been given for a short time. One grain of the extract represents 10 grains of the fresh thyroid. This little patient has been taking 1 grain of the extract daily during the past six weeks without any ill effects.

Though there is no marked change in the different measurements of the head and body made at the beginning of the treatment, I am able to notice a distinct improvement in her physical and mental condition. The hair is assuming a natural gloss, the face has a more intelligent expression and is less bloated, she is brighter, and, when supported, she can stand on her feet for some time. The time is yet too short to enable me to arrive at positive conclusions, but I feel confident that thyroid feeding in this case will in time bring about a normal condition of affairs.

THE DELIRIUM OF CONVALESCENCE.

By LAMBERT OTT, M.D.,
OF PHILADELPHIA.

THIS condition, the delirium of convalescence, apparently paradoxical, is a truism and a rarity, and when encountered gives the physician no little annoyance because, being an unusual concomitant of the stage of improvement in disease, suggests the possibility of the development of an impending attack of insanity. The delirium of disease in its inception and height is a natural and expected association, but to have it continue when other symptoms have abated and the patient has emerged from a dangerous condition and is declared safely over his trouble, or to have a delirium set in for the first time when the patient has reached such a stage is often perplexing and at times suggests a suspicion of a concealed dyscrasia foreboding further mischief.

In some cases of delirium accompanying the stage of improvement of disease it is surprising how often one notices a striking resemblance of an attack to delirium tremens, which I believe it often is. One often finds that a patient has been in the habit of taking from three to five drinks of whisky daily for years, and when he is bedfast for a time, the stimulant having been withdrawn, he progresses favorably through the disease with no mental wandering, but as his condition begins to improve and everything points to an undoubted recovery, he unexpectedly talks discursively, has hallucinations, and gradually manifests all the rational symptoms of delirium tremens. The patient is not known as a drinking man, nor does the physician dare to mention the real nature of the attack, but with potent doses of chloral and bromids to induce sleep the mind becomes normal and he is soon about. Such an attack occurring in the decline of a disease, especially where delirium is to be feared by reason of it indicating metastasis or the extension of the disease to vital brain centers, is viewed with misgivings, and for a time surrounds the issue with an element of doubt.

The following is illustrative of the above facts:

K., aged fifty-eight years, had tonsillitis. The second day the condition of his throat was better and the fever subsided, when a redness and swelling appeared on the nose. The next day the redness spread to both cheeks and fever set in, the temperature not going higher than 103° F., and thereafter the symptoms ran the usual course of an ordinary attack of facial erysipelas. On the fifth day the fever subsided, the tongue became moist, and the pulse normal. The patient now presented every appearance of being well, when, on the sixth day, his mind wandered, he became sleepless, delusions multiplied, and on the seventh day his hallucinations were those ordinarily met with in *mania-a-potu*, though subdued in form. He had no headache, there was an entire absence of fever, the pulse was excited and rapid, there was no vomiting, the tongue was moist, and the urine normal. Chloral and bromids, in 10-grain doses, every hour until sleep was induced dissipated these symptoms, and he was soon convalescent. This condition simultaneously appearing with that of an erysipelatous redness on the head naturally caused no little alarm, and the patient's family felt that inflammation of the brain had set in, nor did I feel absolutely certain as to the cause of the phenomena, but in view of the negative signs I contended that there was no inflammation of the brain coverings, as the issue of the case proved. The delirium was not the wandering of meningitis but more like that met with in alcoholism.

In the apical pneumonia of children, aptly called cerebral pneumonia, there is usually an accompanying delirium of a low, persistent type, at no time violent or excitable, continuous throughout the course of the attack, and not dependant upon the severity of the disease, nor requiring a decidedly elevated temperature to produce it. The association of this form of pneumonia and passive delirium is nearly constant, and even after convalescence is established I have seen the mental wandering continue, always being attended by a rapid pulse and anemia. After a course of tonic treatment the patients have usually recovered.

I have seen delirium in the convalescent period of typhoid fever even in patients manifesting no mind disturbance during the height of the malady. In such patients we find a profound anemic state, and very likely if no vicious family predisposition is present, the faulty brain nutrition is contributive to the condition, the mind becoming normal, as the system regains a healthier tone. Typhoid fever is most productive of the delirium of convalescence, then comes pneumonia, and next severe attacks of scarlet fever. In scarlet fever of an anginose variety, when the convalescence is retarded by complications and sequelæ, such as rheumatism of the joints, serous-membrane inflammations and tubal nephritis, prolonging the disease and consequently impoverishing the blood and lowering the vitality, a low mental wandering is manifested even after all unfavorable systems are removed, and one notices a gradual subsidence of the hallucinations as the systemic condition improves. I have seen the same condition in severe cases of measles, when great prostration, glandular swelling, and anemia accompanied the improvement following the immediate attack. One is constrained to suspect some hidden complication, such as catarrhal pneumonia, in these cases, but in several instances in which delirium, or, I might say, a mental wandering, existed, I was unable to find any lung complication whatever. The patients all improved slowly under predigested nourishment, stimulants, absolute rest, and strychnin. The family history in this class of cases is negative, but a low order of mind usually exists, and it is therefore likely that a feeble-minded child in health is less able to withstand the perverse brain nutrition induced by severe and prolonged attacks of the continued and eruptive fevers, or by lung inflammation.

The delirium of convalescence is a transient delirium with lucid intervals, and has the peculiarity of not being persistent, nor is the patient beyond persuasion of the error of his delusion. His attention can be gained and retained with an effort, and the mind with some aid and guidance operates in normal channels, but left to itself the wandering is resumed.

There are several conditions present in these cases, such as a rapid and feeble pulse, anemia, great prostration, subnormal temperature, and a weakened peripheral circulation, as shown by the cold and pallid extremities. The slightest exertion, as assuming the erect posture, or drinking hastily, induces dyspnea. Occasionally vomiting is an attendant symptom, and this added to the previously described condition, is suggestive of tuberculous meningitis, but an absolute absence of headache enables one to exclude this possibility. It is not always easy to arrive at a definite conclusion but as the case progresses a diagnosis is readily made. One noteworthy fact is the great alarm of the family when it is patent to their minds that the ill one has safely passed through the attack of disease.

As to treatment, strychnin, three times daily, and, in children, a palatable red wine pushed to toleration, produces the most happy effect. Iron is indicated, but if the stomach does not received it kindly then I depend upon rest, stimulants, and nourishment, watching the secretions, and for the development of complications which are always insidious in their approach in these states of lowered vitality.

ACUTE SOFTENING OF THE PONS, RESEMBLING OPIUM POISONING.[1]

By THEODORE DILLER, M.D.,
OF PITTSBURG.

Symptoms resembling opium poisoning may result from softening of, or hemorrhage into, the pons. In a brief but very instructive paper published recently, Dana[2] has analyzed a large number of cases of hemorrhage into the pons, and called attention to the fact that acute lesions of this organ have, a number of times, been mistaken for opium poisoning, and he is able to cite several instances of this sort.

The symptoms which are alike in these two conditions are: coma or stupor, greatly contracted pupils, and a slow rate of respiration. Given the case of a patient exhibiting these symptoms and without a history, a diagnosis would be difficult or impossible; and of the two acute lesions of the pons, it would seem that the difficulty of differentiating from opium poisoning would be greater in the case of softening than in that of hemorrhage, for in the latter instance the sudden onset would very likely greatly aid in clearing up the diagnosis in any case with medico-legal bearings. Of these two lesions, softening is of much more frequent occurrence than hemorrhage, and it is rather surprising that the resemblance of its symptoms to those of opium poisoning has received such scant notice in text-books and current literature, the chief attention being directed to the rarer condition, hemorrhage. It is well known that acute lesions of the pons, produce different symptoms, depending upon the size and location of the lesions, and I do not wish to be understood as maintaining that the symptoms resulting from acute softening always produce symptoms resembling those of opium poisoning, but only that they may do so—how frequent it would be difficult to state. Aside from these medico-legal considerations, the case I wish to report is, I believe, of considerable interest purely from a clinical point of view. Its chief features, briefly, are as follows:

Mrs. B., aged sixty-six years, on the evening of March 7, 1896, was seized with severe cramps accompanied by vomiting. Dr. Thos. Kirk, who was called to see her, prescribed one-eighth of a grain each of morphin and calomel, to be taken every two hours. The patient continued this treatment for about twenty-four hours, taking during this time about one grain of morphin, when it was discontinued. On the evening of March 9th her husband was killed by a street car. She was at once informed of this fact, but she soon forgot it, and was retold of it several times during the evening, only to forget it again. Dr. Kirk then noted for the first time that her pupils were contracted. The next day she was somewhat stupid or lethargic. This condition grew upon her during the next twenty-four hours, at the end of which time she was in almost complete coma.

---

[1] Read at the Twenty-third Annual Meeting of the American Neurological Association, Washington, D. C., May 4, 1897.

[2] *The Post-Graduate*, vol. xi, No. 7.

When I saw her on March 12th, with Dr. Kirk, she had been comatose for forty-eight hours, with slow, irregular respirations, greatly contracted pupils, and twitching of the muscles of the face. The coma, however, was not complete, for a painful stimulus caused withdrawal of either arm or leg, and an expression of pain on the face. The pupils were so contracted that they would ordinarily be described as "pin-point pupils," but more accurately, I think, as "pin-head pupils." A convergent squint was present. There was a good deal of twitching of the muscles about the mouth. The respirations were about seven or eight to the minute, and came in pairs of threes, with long intervals between each group. Her temperature, which on the 7th was 103° F., had come down until the 10th, when it was 100° F. It then slowly rose and was 101.5° F. on the 12th. She continued in the condition described until her death which occurred the next day. It was a source of much regret to both Dr. Kirk and myself that an autopsy was refused.

The morphin given during the attack of gastroenteritis, which was the beginning of the patient's illness, was most carefully administered, and there can be no doubt that the amount taken was as above stated, and that none was given after the first twenty-four hours. Mental confusion was noted about the time the morphin was discontinued. Stupor began twelve hours later and gradually grew deeper, but twenty-four hours elapsed before this stupor developed into actual coma, and the coma was never complete. These facts alone, had the case been a medico-legal one, would have sufficed to show that the symptoms were not due to morphin poisoning.

The points laid down by Dana which distinguish an apoplexy of the pons where there are contracted pupils, slow respirations, and coma from opium poisoning, were well illustrated in this case. According to this authority opium poisoning is characterized by a rise of temperature of from .5° to 1°, there is no twitching of the muscles, the respirations are slow but regular, and coma is complete, while in apoplexy of the pons there is a rise of temperature of from 3° to 4°, twitching of the face muscles is present, the respiration is irregular or Cheyne-Stokes in character, and coma is incomplete.

In the case reported, another symptom of considerable importance was present, *viz.*, an internal squint; and this, taken in connection with the other symptoms, strengthens the correctness of the diagnosis arrived at—acute lesion of the pons. The gradual onset of the cerebral symptoms of course indicated softening rather than hemorrhage. The early rise of temperature, due to gastro-enteritis, the subsequent fall, with abatement of the gastro-intestinal symptoms, followed by a rise during the first two days of coma, are interesting features. What to me seems a reasonable explanation of these facts is the following: A condition of the cerebral vessels favorable to the formation therein of a thrombus was present, and the fall of temperature was due to a subsidence of inflammation; but during this time a thrombus formed in the pons, favored by the altered condition of the blood, softening followed, and with it coma, and a second rise of temperature.

A CASE OF LEAD POISONING PRESENTING SOME UNUSUAL EYE SYMPTOMS.

By CASEY A. WOOD, M.D.,
OF CHICAGO;
PROFESSOR OF OPHTHALMOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL.

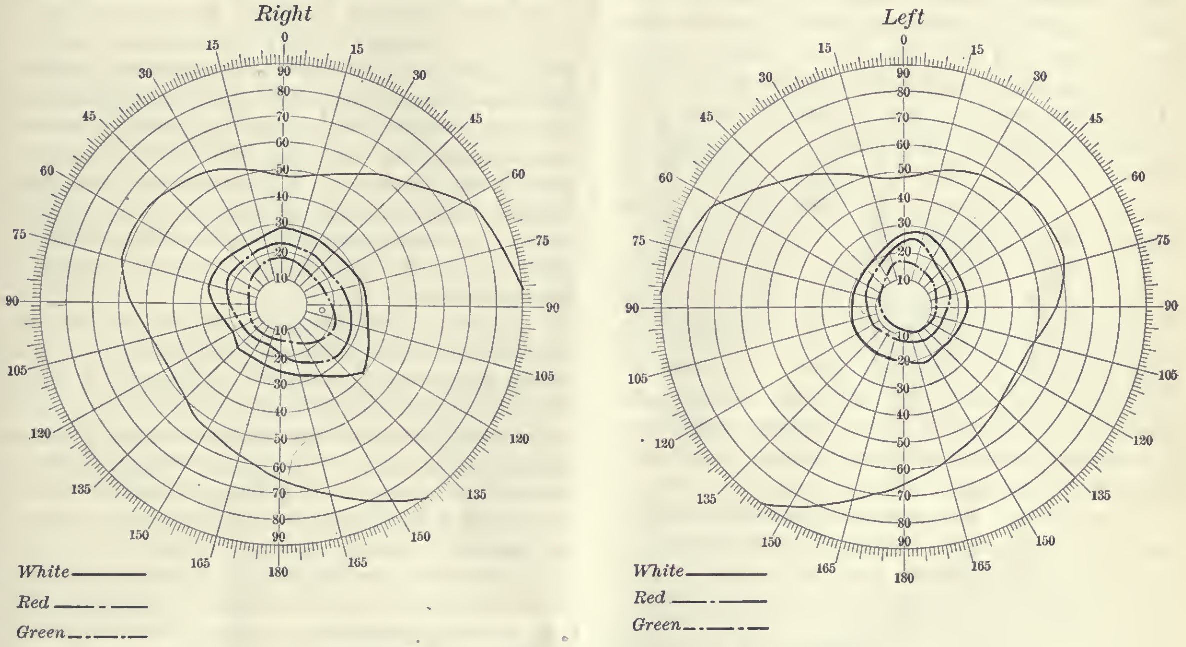
ALTHOUGH ocular symptoms, as a result of plumbic intoxication, have been recognized and studied for over two centuries attention has been chiefly directed to the visual defects arising from the fundus changes, especially inflammation or atrophy of the optic nerve. In recent years a transient amblyopia, not attended by any lesion visible to the eye and comparable to the temporary blindness of uremia or diabetes, has also been recognized and frequently reported. Various forms of retinitis, too, have been observed, and these are believed by Parisotti[1] to be due to a form of endovasculitis which he terms *endarteritis saturnina obliterans*.

Another class, possibly rarer than the foregoing, includes instances where the intoxication produces paralysis of one or more of the extrinsic ocular muscles. The following report is of such a case:

Jacob B., aged forty-nine, has steadily followed the occupation of painter for sixteen years, doing both inside and outside work during that time. He has enjoyed fair health and the only history of illness, apart from the attacks about to be described, is that of typhoid fever many years ago, followed by a large carbuncle in the lumbar region. He is married and has had five children, of whom one died at six months of age. There is not now any evidence of syphilis in his own person or that of his wife or children. He has had no injury to the head nor is he the subject of any lesion of the brain or cord. He has, however, had several attacks of what seemed to be true painter's colic. The first of these come on five years ago, and the last one six weeks ago. There has never been any weakness of the extensors of the hands, approaching the condition of "wrist drop," but he speaks of having noticed a slight tremor of the hands and a weakness of grasp. There is no definite history of transient attacks of defective vision. Three years ago, on rising one morning, he became dizzy and fell. He says he remained unconscious for half an hour, after which he felt a dull pain which extended over the whole head, lasted two-days, and then gradually disappeared. Since then he has had persistent double vision, and occasional attacks of vertigo. Three weeks after this last attack his left eye began to turn out, and the left lid has drooped so that the eye is almost closed.

His present condition is as follows: his left eye has vision $\frac{2}{5}$, not improved by glasses. With + 3 D. he reads words of Jæger 1. There is complete *ophthalmoplegia externa*, with the exception of the external rectus and possibly of the superior oblique. The paresis of the levator labii superioris is most marked when he is not fixing his eyes. The pupillary reflexes of both eyes are sluggish to light and accommodation. With the ophthalmoscope very few fundus changes are visible, but the outlines of the papilla are not clean cut, and it has a woolly appearance. There are a few patches of disturbed choroidal pigment scattered over the fundus. fitting hernial truss. The patient's urine and saliva are practically normal. In testing for lead the dihydric sulphid, potassic iodid, and potassic chromate reagents are employed.

To me the most interesting signs of plumbic intoxication in this case are the unilateral pareses, and the fact that the optic-nerve atrophy set in without any of the transient attacks of amblyopia which usually precede the permanent disease. The treatment has consisted of hot baths, small daily doses of magnesic sulphate and potassic iodid; of the latter one gram three times a day, gradually increasing it until nine grams *per diem* were administered. The patient has not been working for the past six weeks. Some improvement in the muscular signs has already resulted.



Right *Left*

Contraction of visual field as a result of chronic lead poisoning.

There is nothing abnormal about the right eye except the lazy pupillary reactions and slight fundus changes resembling those of the left eye. V=$\frac{2}{3}$, and Jæger 1 is easily read with + 3 D.

The visual field of each eye is decidedly contracted, the limitations being more marked in the left eye. (See Figs. 1 and 2.) The patient now presents none of the classic signs of plumbism, wrist drop, muscular tremors, blue lines along the gums, etc, but, on the other hand, he has not worked at his trade for some time past.

Dr. Sanger Brown reports that, with the exception of the oculomotor paresis and the optic-nerve defects, there is nothing abnormal about the patient's nervous apparatus. There is absence of patellar-tendon reflex on the left side, but this, Dr. Brown thinks, may be due to his wearing a powerful and ill-

The above is the only instance of saturnism affecting the third nerve that I have observed among nearly 13,000 cases of ocular disease that have come under my immediate care, but I think it is quite possible that I have attributed to syphilis and other causes, examples of ocular paralysis that were really due to lead poisoning. When one thinks of the numerous sources of lead intoxication to which the public is exposed (from food and drink stored in leaden vessels) and of the many crafts in which lead is continually used, examples of oculomuscular defects due to plumbism must be far from rare. However that may be, the reported cases are not numerous. Galezowski[2] reports several of these and thinks they constitute a large percentage of saturnine ocular intoxications, and that they are particularly unsatisfactory to treat if all the branches of the third nerve are implicated. Incomplete pareses, on the other hand, are more amenable to remedial measures. Landesberg[3] reports a case of bilateral paresis of the external rectus, while another patient observed by him had complete paralysis of all branches of the oculomotor nerve. Von Schröder[4] also reports a case of typical neuroretinitis with bilateral abducens paralysis. Wadsworth[5] gives a very instructive account of a boy, aged 9, in whose urine lead was found for many months, although the source of the poison was never ascertained. He had marked optic neuritis and paralysis of several ocular muscles, and eventually became blind from optic atrophy.

It is not difficult to understand why the eye muscles should occasionally suffer in chronic lead poisoning. One of the most characteristic signs of the disease is an affection of the voluntary muscles in other parts of the body, and there is no reason why the motor apparatus of the eyeball should escape. The case reported by Parisotti furnished, by means of the ophthalmoscope, an opportunity of studying the minute changes as they actually progressed in the capillary system of the fundus oculi, while the comparatively frequent occurrence, in chronic plumbism, of retrobulbar neuritis leads us to believe, with Oeller[6] and others, that whenever secondary alterations set in the process *begins* as a fatty metamorphosis (obliterating peri- or endarteritis). As I have previously pointed out,[7] the nervous, muscular, and other tissues supplied by these nutrient vessels may be converted into fat, fibrous tissue or hyalin substance as a secondary metamorphosis.

The ocular lesions in chronic plumbism are, then, essentially peripheral in character, and are quite distinct from, although they may be coincident with, other eye alterations which sometimes occur as a result of renal and cerebral complications arising in the course of a long-standing intoxication.

CLINICAL MEMORANDUM.

EXSTROPHY OF THE BLADDER WITH OTHER CONGENITAL DEFECTS; MAYDL'S OPERATION.[1]

By ROSWELL PARK, M.D.,
OF BUFFALO;
PROFESSOR OF SURGERY AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO;
SURGEON TO THE BUFFALO GENERAL HOSPITAL.

During March, 1897, there was sent to me by Dr. Williams of East Otto, N. Y., a boy four years of age, presenting a case of exstrophy of the bladder, with other congenital deviations, which seemed to make it worthy of a special report. The boy was well-nourished and of strong frame in all respects save those below noted. There was a deformity in the pubic arch of just two inches, the bone being replaced by fibrous tissue. The presenting area of the bladder was about the size of a silver dollar, both ureters presenting as papillæ, from which, even on coughing or sneezing, a little jet of urine was projected. At the upper margin of the mucous membrane was seen all that presented of the umbilicus, which appeared as a semilunar cicatrix. The penis was rudimentary and there was complete epispadias, a deep groove taking the place of the urethra. The right testicle was completely undescended and the left had remained in the inguinal canal. There was incontinence of fluid feces, and a tendency to prolapse of the rectum, due to an exceedingly weak sphincter.

I saw no prospect, under the circumstances, for any successful plastic operation, and consequently determined to turn the ureters into the colon, as suggested by Maydl. This was done in my clinic, chloroform being the anesthetic used. I first dissected away the rosette of mucous membrane around the ureters, leaving a small oval portion of the bladder wall and mucous membrane, which included the ureteral orifices. All this was done by careful dissection before opening the peritoneum; then protecting the parts by temporary compression of the ureters, I opened the peritoneum and at once came upon what at first appeared to be the stomach, so thick were its walls and so deceptive the appearance of its vessels. Further investigation showed this to be an enormously dilated colon, which lay almost in the middle line, and which extended straight up toward the sternum. Following it downward, it narrowed to a very small compass, where it became continuous in the pelvis with what, by bimanual examination, proved to be the rectum. It was then seen that a marked congenital defect of the large bowel existed along with that of the bladder. Nevertheless, there was now nothing left to do but to proceed. Accordingly this dilated colon was opened at a suitable point and compression removed from the ureters, after which they were implanted in the colon and anchored, and the wound about them made tight by fine silk sutures. It was then impossible to cover the comparatively small abdominal wound by lateral approximation, so I closed it at a right angle to the ordinary line by silkworm-gut and kangaroo-tendon sutures, leaving still a raw surface over which the skin could not easily be drawn. Then, in order to close this, I extirpated the spongy tissue of the rudimentary penis and utilized the integument of its lower surface as a flap over the defect above, which it completely and neatly closed.

---

[1] Read by title before the American Association of Genito-Urinary Surgeons, Washington, D. C., May 5, 1897.

During the first twenty-four hours the boy did well, passed urine freely from the rectum, and complained but little. During the second night his stomach became disturbed, and on the following morning rejected everything. When I then tried to feed him by the rectum, it was found impossible to make the rectal pouch retain anything, because of the weakness of the sphincter, while to expose the opening between the rectum and the colon above, in order to pass the enemata higher, would have been impossible without chloroforming him and using a speculum. The result was that the boy died about fifty-five hours after the operation, during the last eight or ten of which apparently no urine was secreted, certainly not passed.

A hurried autopsy was permitted, which revealed the absence of any evidence of peritonitis, and showed the bowel condition to be about as outlined during the operation. The rectal pouch communicated by an opening, which would ordinarily admit a lead-pencil, with a large, thick-walled, and much distended colon, that extended toward the liver and had no splenic flexure.

The case illustrates beautifully the embryonic condition by which the lower opening of the alimentary canal is produced, as is the upper, *i.e.*, by an infolding of the surface and a communication with the primary tube, which is later established. In this case the opening was established, but proved utterly inadequate in size for the desired purpose; hence, I take it, the coincident deficiency of the sphincter. Whether the condition of the colon was also a return to simpler conditions and was an evidence of atavism, or whether it had been straighted out as the result of pressure, I could not make out, the autopsy having to be made under most unsatisfactory conditions.

So far as the principal procedure is concerned, I am inclined to think it worthy of performance in any case where the condition of the genito-urinary organs is as rudimentary and defective as in this. The operation of itself means, in effect, a restoration of the urinary canal to the avian type, and makes of the colon and rectum what they really are in birds, namely a cloaca. Should such complications as were met with in this instance be found, the case would necessarily assume from the outset an almost positively fatal aspect. To have turned the ureters into such a rectum as this patient had would have been impossible, while to have determined exactly the bowel condition would have been out of the question previous to a combined examination with the aid of an anesthetic.

A Conference on Balneology and Climatology.—The Russian National Health Society proposes to celebrate, next year, the one hundredth anniversary of the discovery of the mineral springs of the Caucasus by a conference on balneology and climatology.

MEDICAL PROGRESS.

A New Source of Conjunctivitis.—DESPAGUET (*Bull. Médic., No. 89*) has called the attention of the Paris Society of Ophthalmology to a special and as yet undescribed form of conjunctivitis due to infection from animals, or rather from the remnants of slaughtered cattle. He has noticed it among butchers and those people dwelling in the vicinity of slaughter-houses. The inflammation is usually limited to one eye, and consists in a kind of glandular swelling of the conjunctiva, together with considerable number of granulations of the eyelids and eyeball, which, on pressure, exude yellowish pus. The cornea is unaffected and there is no pain, but the eyelids are swollen. As a concomitant symptom, there is more or less swelling of the parotid and of the cervical glands which sometimes even suppurate. The treatment employed was that of iodoform salve and hot compresses locally, and sulphate of quinin internally. After fourteen days considerable improvement was noticed.

ABADIE also has had considerable experience with this form of conjunctivitis, among butchers especially. He has had several cases under observation in which the disease affected both eyes, and has also observed that it often occurs in an epidemic form.

A Diagnostic Sign of Fecal Tumors.—GERSUNY calls attention in the *Wiener Klin. Wochenschr.*, Oct. 10, 1896, to a symptom of fecal tumors, that is to say, of tumors formed by the accumulation of fecal matter in the large intestine. The symptom is due to a peculiar sensation which one receives by pressing deeply with the finger tips against the tumor and then withdrawing the fingers very slightly. The intestinal mucous membrane is pressed by the finger tips against the fecal matter, and when the pressure ceases, it resumes its former position, giving to the fingers a characteristic sensation.

The sensation is described as being similar to that experienced if the finger tips are covered with grease and first applied and then withdrawn from the palm of the opposite hand. Several conditions are necessary in order to produce this phenomenon in connection with fecal tumors. The mucous membrane must be sufficiently dry; the fecal mass must permit the fingers to press into its substance a little; and there must be sufficient gas to cause the intestinal wall to resume its original position when the pressure is relieved. Finally, when all these conditions are present, palpation must be made with great delicacy. Gersuny has verified this symptom in three cases of fecal impaction.

Is Albuminuria a Contraindication for Nursing?—As the children of women who suffer during pregnancy from albuminuria are usually poorly developed, and are often delivered before time, they, more than others, are in need of their natural nourishment—mother's milk—so that the question is a practical one, whether or not they are to be nursed by a woman who suffers from albuminuria to such an extent that she has to be placed on a milk diet. Most physicians forbid this, but GAMULIN (*Centralbl. f. Gynäk.*, No. 46, 1896), who has collected 138 cases under

Pinard's direction, reaches an opposite conclusion. He finds that the children of women with albuminuria who are brought up on the breast are as well developed and increase as rapidly in weight as others, and to all appearances are in nowise affected by the nephritis or the general condition of the mother. An exception is to be made in those cases in which, in spite of milk diet, the mother's albuminuria does not improve.

Suture of the Lateral Sinus.—The suture of large veins, when wounded, is a surgical procedure which very recently has come into practice, and, like the ligature and clamp to control hemorrhage, was suggested by the exigencies of operations, attempts being made by surgeons to preserve the patency of large veins in order to obviate the disadvantages, perhaps death, which would follow their closure. Successful experiments upon animals have been reported from time to time during the last eight years, and many surgeons have obtained good results by suturing the axiliary, femoral, internal jugulars, and other large venous trunks. One of the most interesting of these successes was the suture of the inferior vena cava by Schede, after its injury, in an operation upon the kidney. At autopsy, some time later, it was seen that the stitches had held perfectly, and that the lumen of the vessel was well preserved. But so far as known, Schwartz records (*Gaz. Heb. de Méd. et de Chir.*, Oct. 22, 1896) the first successful attempt at suture of the lateral sinus. His patient was a man, aged twenty-six, who presented himself with necrosis and a sinus behind the left ear, following a kick from a horse received three months before. At the operation (November 24, 1895) a piece of bone, the size of a silver dollar, was found depressed. It was adherent in part to the dura mater, and, despite every care, the lateral sinus was opened during its removal, a rent nearly half an inch in length being made. Hemorrhage was profuse, but when two fine silk stitches placed in the wounded vein were drawn tight the bleeding was controlled. The wound was lightly tamponed with iodoform gauze, and the patient made a good recovery. The central portion of the depressed area of bone was necrotic, and it was at this point that the adhesion to the sinus existed.

Suppurative Pericarditis Treated by Incision and Drainage.—Bohm (*Dutsch. Med. Wochenschr.*, Nov. 26, 1896) gives the history of a patient in whom a suppurative pericarditis developed as a sequal to influenza and pleuropneumonia. Internal medication was of no avail and death seemed imminent. One month after the beginning of the disease the pericardial sac was opened in the third intercostal space a finger's breadth from the sternal margin. More than a liter of pus and fibrinous masses was evacuated. The contents of the sac had evidently been under considerable pressure. An attempt to insert a drainage tube was abortive. The tube constantly pushed out again. The cavity was therefore drained with iodoform gauze. On account of the wretched condition of the patient the operation was performed under cocain.

The patient rapidly improved. For one week the pericardial sac was washed out with a solution of boracic acid. The opening in the pericardium closed in three weeks. Recovery was retarded by two exacerbations of the inflammatory process of the left lung. Three months after the pericardiotomy the condition of heart and lungs was once more nearly normal. One month later the patient resumed his ordinary work.

This is the fifteenth case of pericardiotomy on record. Eight of these recovered. Of the seven deaths, one in a very weak patient was apparently caused by the mechanical shock of the irrigating fluid upon the already weakened heart. One patient died thirty hours after operation, and the autopsy showed extensive fatty degeneration of the heart muscle. In one of the remaining five deaths there were abscesses in the myocardium which communicated with the pericardial cavity. In the others, death resulted from serious complications, extensive pneumonia, empyema, nephritis, etc.

It is worth noting, therefore, that of those cases in which the pericarditis was primary or only complicated by a left pleurisy, only one died; while of those in which the pericarditis developed only as a symptomatic affection in connection with pyemia and septicemia, only one recovered. From this it is perfectly plain that the operation of pericardiotomy is a relatively simple one, and ought to occupy the first place as a therapeutic measure in suppurative pericarditis. Why, then, should any surgeon hesitate to acknowledge in connection with inflammations of the pericardium the truth of the old principle *ubi pus ibi evacua* since the old prejudices against the operation have proved themselves to be merely prejudices?

THERAPEUTIC NOTES.

THE AMERICAN MEDICAL ASSOCIATION.

THE jubilee meeting of the Association at Philadelphia next week promises to be an unusually enjoyable and interesting occasion. The officers of the sections seem to have vied with each other in their efforts to secure vigorous discussions of the most vital questions of the hour pertaining to each department. No more convincing assurance is needed that the Association is fulfilling the lofty aims of its founders than is revealed in the program of the scientific part of this semicentennial meeting.

The anniversary exercises will afford a unique feature. The narration of the early history of the organization, the circumstances surrounding the inception of the original idea, the objects to be attained, the early struggles to place it on an enduring basis, the enlisting of congenial spirits whose efforts should carry it forward to completion, and, finally, the contemplation of the result, after fifty years of existence, cannot fail to supply themes replete with interest and pregnant with inspiration for future achievement.

The hospitable doors of Philadelphia have been thrown wide open to receive her guests, and the social functions of the occasion are not the least inviting feature of the program.

Much of the success of these meetings depends upon the ability and energy with which the Committee of Arrangements performs its work. Under the leadership of its chairman, Dr. Hare, the committee has been successful in locating the various section-meetings in comfortable and appropriate quarters convenient to the main assembly hall and within easy reach of each other. By this careful forethought much time will be saved to the members, and the several sections will be enabled to begin and close their sessions promptly, thus avoiding any interference with the general sessions.

In the MEDICAL NEWS of May 22d may be found a convenient map of the city, giving the location of the various places of meeting, the principal hotels, points of interest in the city, etc.

A promising sign of the prosperity of the Association is to be found in the fact that various cities are vying with each other to secure the honor of entertaining it at its annual meeting. Denver, Colorado, is already in the field with a most cordial and tempting invitation for next year.

THE DISPENSARY ABUSE.

IN another column of this issue of the NEWS will be found the report of the Special Committee of the Medical Society of the County of New York on the Abuse of Medical Charity. There is much in this report, as there was in the discussion preceding its acceptance, that will bring home to the profession a keen realization of the unpardonable abuse of medical charity by those who are unworthy of its benefits and a knowledge of the attitude of the governing boards of hospitals and dispensaries toward efforts at reform. The issue is now clearly defined, the reforms necessary to correct the abuses are apparent, and the means of putting them in motion are plainly set forth.

The members of the committee are to be congratulated on the broad grasp of the subject which their work reveals, and the logical steps by which they pursued it to the the final drafting of a bill which met the unanimous approbation of both houses of the Legislature. That it failed to secure the approval of the Governor is no reflection upon the merits of the bill *per se*, although the careful study and consideration which it will doubtless receive before its reintroduction to the Legislature may suggest valuable improvements.

The enthusiastic endorsement of the work of the committee by the County Society cannot but strengthen the efforts that will be made in the future to obtain favorable legislation along the lines so much desired.

This action is not local, nor is it confined to the State of New York alone. The County Medical Society has set its seal of approval upon the first well-organized attempt in this country to deal adequately and forcibly with this great question of medical economics. During thirty years of medical development and progress this abuse has been growing, and each effort to lessen it has apparently served only to instil into it fresh vigor and virulence. The responsibility of assuming the burden of the fight is great, and throughout this broad land the eyes of the entire profession will be directed toward this society, with every confidence that its efforts will ultimately be crowned with success.

The amount of work performed by the committee was something prodigious, and, as suggested by the presiding officer, DR. LANDON CARTER GRAY, the details would make very interesting reading, if it were a matter of policy at this time to make them public. The signing of the bill giving control of dispensaries to the State Board of Charities, an impartial tribunal that could be depended upon to justly and equitably use its powers, was secretly opposed by an influence that in the end was successful. But now that the guns of the enemy have been unmasked, the Committee on the Abuse of Medical Charity of the Medical Society of the County of New York will be well prepared to begin the battle anew, and the best wishes of the profession throughout the country will be with it. Legislation is the only remedy, and this is sure to be achieved sooner or later, in spite of all opposition.

SILVER WIRE AS A SUTURE IN SURGERY.

NEARLY half a century has elapsed since J. Marion Sims conceived the idea of using silver wire as a suture in the treatment of vesicovaginal fistula. No sooner was the idea grasped than his fertile mind began devising ways and means for putting it into application, and a willing patient promptly submitted to its experimental use. After twenty-nine failures with various suture material, the thirtieth operation, performed upon this woman, proved permanently successful.

Not only was this the first case in which a cure was achieved by this distinguished surgeon, but it was the first successful operation for the relief of a vesicovaginal fistula ever performed in the history of surgery. No wonder, then, that Dr. Sims attributed the brilliant result to the one new factor, silver wire, and no wonder, also, when similar results crowned his efforts in succeeding operations done with the same suture material, he stood ready to announce the edict that the use of silver as a suture was the great surgical achievement of the nineteenth century.

Undoubtedly the use of silver wire in those early cases, with only the crude appliances which he himself devised, and before anything was known of sepsis and asepsis in surgical work, was the factor which gave him success. Why it succeeded in the very cases in which silk suture had failed, was only explicable to him on the ground that silk acted as a seton, while silver did not. The immediate followers of Dr. Sims accepted his edict that silver wire was the only suture that could be used successfully in vesicovaginal fistula, and used it without further inquiry into the *rationale* of its action.

As the operation became better understood, and specula and other instruments better adapted to their purpose came into use, operators in various fields were able to secure satisfactory results with suture material other than silver wire; so the sentiment gradually grew that Dr. Sims' success was due rather to the fact that he had better facilities for doing his operation, and had attained greater skill, than to the nature of the suture material.

Within the past year, however, a satisfactory explanation of the success attending the use of silver wire as a suture has come most unexpectedly from a foreign source. Dr. B. Credé, attending surgeon to the Carola Hospital of Dresden, in an address delivered before the National Surgical Society of Germany, at its twenty-fifth annual convention, held at Berlin on May 28, 1896, discussed silver and its salts, the citrate and lactate, which he termed the *itrol* and *actol*, and pronounced them the most powerful of all the surgical antiseptics yet discovered. It appears that his interest in silver as an antiseptic grew out of the observations of his father, the elder Credé, on the value of the nitrate of silver in the treatment of inflammatory affections of the eyelids of infants.

Nitrate of silver was not a success as a surgical dressing, however, on account of its chemical instability and its corrosive action on mucous membranes. While visiting the Johns Hopkins Hospital, in Baltimore, Dr. Credé was impressed with the use of silver foil as employed by Dr. Halsted, in affording an antiseptic covering for small or closed wounds. His next experiment, therefore, was made with metallic silver, using it as an antiseptic dressing for wounds. When applied to a sterile wound, he found that it remained unchanged, was non-irritating, and formed a thoroughly aseptic dressing. On the other hand, when applied to an infected wound, the products of bacterial life oxidized the surface of the silver, and, entering into combination with the argentic oxid, formed argentic albuminates, which had powerful antiseptic properties. Careful analysis developed the fact that it was lactic acid which was developed in the microbic secretions, and that when this combined with the silver oxid there was developed a lactate of silver, and in this resided the antiseptic properties.

In this discovery lies the explanation of the value of silver wire as a suture. In aseptic, sterile wounds it is non-irritating and remains unchanged. In infected wounds it supplies in itself the base of a powerful antiseptic, combining with lactic acid, and forming thus in the tissues the lactate of silver.

The experience here recorded illustrates the principle so often insisted upon that clinical observation has its legitimate field and is a faithful guide, although the scientific explanation of the conditions and results observed are not, at the time, susceptible of a rational explanation. Sims' prophetic soul rested in the belief that some day a rational explanation of the fact he asserted would be forthcoming, and in this recent discovery of Credé it seems to be fulfilled.

ECHOES AND NEWS.

The Craig Colony for Epileptics.—The bill appropriating $171,000 for buildings for the Craig Colony for Epileptics in New York has been signed by the Governor.

The New York Medical College for Women.—This institution held its thirty-fourth annual commencement exercises May 13th, and conferred diplomas upon seven graduates.

Honors for Drs. Welch and Osler.—At the annual meeting of the Academy of Arts and Sciences, May 12th, Drs. William H. Welch and William Osler were elected Associate Fellows in the Section of Medicine and Surgery.

The Duchess of Teck.—It is reported that the Duchess of Teck has been subjected to an operation for strangulated umbilical hernia. The operator was Mr. Herbert Allingham. No complication has arisen and recovery seems assured.

Yellow Fever at Quarantine. — When the steamer "Finance" arrived at New York from Colon, May 21st, it was reported that there had been one death on board from yellow fever. The eighty-eight passengers and crew were held for examination, and their effects and the steamer were thoroughly disinfected.

The X-ray and the Cinematograph.—Dr. John Macintyre of Glasgow has conceived the happy idea of combining the cinematograph with the fluoroscope and thus studying the movements of bones in living men and animals. If successful in this, there seems to be no reason why it may not be utilized also for studying or determining the heart's action.

Antivivisection in Congress.—Mr. Gallinger has reported favorably, from the Committee on the District of Columbia, the bill "For the further prevention of cruelty to animals in the District of Columbia." This bill proposes onerous and useless restrictions on the advancement of medical science. Every effort is being made, and it is hoped successfully, to prevent the passage of this bill by Congress.

A Medical Board for the New York Department of Corrections.—The visiting physicians and surgeons of the various institutions under the control of the Department of Corrections have organized a medical board independent of the Department of Charities. The board is composed of thirteen physicians and surgeons. Dr. J. P. Tuttle has been elected president, and Dr. P. R. Bolton, secretary.

The Hospital Graduates' Society Dinner.—The annual dinner of this thriving medical society was held Thursday evening, May 20th, at the Union Square Hotel, New York. A most sumptuous repast was discussed to the satisfaction of the hotel proprietor as well as those seated at the hospitable board, after which some instructive as well as amusing speeches were enjoyed, the program being enlivened by well-chosen musical selections.

New Portrait for the New York Academy of Medicine.—Dr. Webster, in behalf of some of the Fellows of the New York Academy of Medicine, presented to the Academy at its last meeting a large and handsome portrait of Dr. D. B. St. John Roosa, a former president. It is by E. Pollak. The gift was formerly accepted by Dr. E. G. Janeway, president of the Academy. It will be hung on the walls of Hosack Hall, with the portraits of other former presidents.

Doctor's Bills in Australia.—An Australian sent his consumptive son to a private hospital in Sidney, where he remained four months and was cured. The doctor sent in a bill for nearly $4000, which the father refused to pay, offering in settlement only $200, whereupon the doctor sued him. After a three-days' trial the case was decided in favor of the defendant. According to Australian law a doctor can sue only when he has a written agreement with a patient.

Nurses Receive Diplomas.—The graduating exercises of the Presbyterian Hospital Training School for Nurses, class of '97, were held at the hospital on the evening of May 13th. There were addresses by J. C. Kennedy, president of the school's Board of Managers, and by Dr. John S. Billings, as well as a lengthy musical program. Dr. Frederick Sturgis presented the diplomas and made an address. About 1500 persons were present. The graduates numbered twenty-two.

Entertainments of the American Medical Association.—In the list of entertainments of the American Medical Association at Philadelphia, published last week, two important ones, which promise to be very agreeable functions, were omitted. The Philadelphia County Medical Society gives a luncheon at the Hotel Walton on Tuesday, June 1st, at one o'clock. On the same day and hour, the trustees and faculty of the Philadelphia Polyclinic give a luncheon at the Polyclinic Hospital, Lombard street, above Eighteenth.

Antitoxin to be Tested.—The New York State Board of Health has decided that hereafter all antitoxin must be tested by the officials of the board before being placed on sale in the State. This is a very important step, as the use of antitoxin as a remedy for diphtheria is growing, and is proving more satisfactory in cases where the antitoxin has been properly prepared and is used with intelligence. The antitoxin sold in the market has been found to be unsatisfactory in some instances, and it is desired that it should be of uniform strength.

The Bubonic Plague.—The doctors sent to India by the Austrian government have reported to the Academy of Sciences at Vienna that neither Professor Yersin's nor Professor Haffkin's serum has been successful in the treatment of cases of bubonic plague. This is entirely at variance with special advices received by the MEDICAL NEWS direct from Professor Yersin through Professor Roux at Paris. Is it possible that such an indefinite report may have been inspired by jealousy of the French investigator, or does the diversity of opinion lie in the definition of what constitutes success?

The Risks and Sacrifices of Medical Men.—A phase of Professor Koch's work worth noting by those who denounce him as a monster because he experiments on pretty little guinea-pigs, is the deadly peril to himself that is incidental to his investigations, and especially in the preparation of his improved tuberculin. His report does not refer to this directly, but he warns other experimenters to remember constantly that they are dealing with the most fatal of bacilli and in their most active state. "The danger is not small," he says, "and I must confess that I have often felt, while at work, as though I were handling dynamite bombs."
